ABSTRACT

Proposed dissertation: HEURISTICS FOR SOLVING THREE ROUTING PROBLEMS: CLOSE-ENOUGH TRAVELING SALESMAN PROBLEM, CLOSE-ENOUGH VEHICLE ROUTING PROBLEM, SEQUENCE-DEPENDENT TEAM ORIENTEERING PROBLEM

William K. Mennell, Doctor of Philosophy, 2009

Dissertation advisor: Professor Bruce Golden
Dissertation co-advisor: Professor Edward Wasil

In this dissertation, we examine three important routing problems. In the second chapter we investigate the Close-Enough Traveling Salesman Problem (CETSP) in which a salesman must get within a specified radius of each node to visit it. The third chapter studies the multi-vehicle extension of the CETSP, the Close-Enough Vehicle Routing Problem (CEVRP). In the fourth chapter, we develop a post-processor to improve the accuracy of our heuristics for solving the CETSP and CEVRP. In the fifth chapter, we solve the Sequence-Dependent Team Orienteering Problem (SDTOP) in which the profit received for each node visited is dependent on the sequence in which all the nodes are visited. We summarize the dissertation in the final chapter.

The CETSP, CEVRP, and SDTOP have application in aerial reconnaissance route planning. We formulate each problem as a mathematical program and apply heuristic and combinatorial optimization techniques to solve them. We present the

results of extensive computational experiments that show that our methods produce high-quality solutions quickly.

HEURISTICS FOR SOLVING THREE ROUTING PROBLEMS: CLOSE-ENOUGH TRAVELING SALESMAN PROBLEM, CLOSE-ENOUGH VEHICLE ROUTING PROBLEM, AND SEQUENCE-DEPENDENT TEAM ORIENTEERING PROBLEM

by

William Kenneth Mennell

Dissertation submitted to the Faculty of the Graduate School of the
University of Maryland, College Park, in partial fulfillment
of the requirements for the degree of
Doctor of Philosophy
2009

Dedication

Dedicated to my wife Amanda, my children Gracyn, Aedyn, any other children that come along down the road, my parents, and to the memories of Paul Ross and Leonard Opper.

Acknowledgments

Two pages is not enough to thank those who have made the completion of this arduous task possible.

I must first thank Amanda, my wife, for sticking with me these last five years, going far above and beyond in many ways I cannot describe here. She and our two little imps, Gracyn Rosena and Aedyn Paul, have loaned me countless hours that could have been spent with them, and I want to begin repaying them. This work has been my life the last few years. Of course I will always be busy, but I finally have the chance to rearrange priorities putting work in its proper place behind family.

I must also thank my advisors, Dr. Bruce Golden and Dr. Ed Wasil, for making this dissertation possible. Dr. Golden, thank you for all the ideas on benchmark methods against which to test my work. Most importantly, and you cannot possibly understand how important this was to me, thank you for allowing me to turn my academic passion, the Close-Enough TSP, into a major portion of my dissertation. Without that, I'm not sure I would have made it this far. Dr. Wasil, you have led this horse to water many times, and many times he has not drunk the water. You dealt with apparently the slowest academic-writing learning curve in history and still managed to maintain civility with me. Thank you for helping me produce a readable dissertation.

Thanks also to Dr. Zhi-Long Chen, Dr. Dave Mount, and Dr. Paul Schonfeld for sacrificing their own time to sit on my committee, read this work, and challenge me to improve it. I will remember that willingness to help, and I appreciate it.

I appreciate Dr. "Raghu" Raghavan's help in letting me take over multiple computers in his lab on which I ran some very long experiments (yes, some of the GA's I ran for comparison purposes really DID run for five months). Thanks to Dr. Raghavan, Dr. Ball, and Dr. Golden, I was able to able to equip the computers with GAMS, MINOS, and battery back-ups to successfully run the many experiments I performed.

Thanks to John Silberholz for his many ideas and willingness to share and discuss them. Thanks to my classmates - Scott Nestler, Kiran Pamchamgam, and Matthew Reindorp - for their friendship and their help keeping this leaky boat from sinking the first few years of classwork. Without your help the first semester, Scott, I think I would not have passed Simulation.

I thank Amy Ciric, Scott Nestler, Kiran Pamchamgam, Matthew Reindorp, Clay Rozic, Yufeng Tu, Wenli Wang, and Fred Zeitz for their comments and suggestions which helped improve the dissertation. Many thanks to Damon Gulzcynski and Jing Dong for providing codes used in our experiments. Thanks to Peter Bodin for making his *bubble plot* Matlab 3D visualization code freely available and to John D'Errico for making the key building blocks to my 3D polygonal Steiner-zone visualization code freely available and for providing some advice on how to modify it.

Thanks to my mentor, Dr. Sam Thangiah, who inspired my interest in vehicle routing and related problems as an undergrad. Thanks also for making some computers available for me to run some of experiments the last few months.

Thanks are also due Dr. Maria Grazia Speranza for providing the data for the

Team Orienteering Problems from which I created my Sequence-Dependent Team Orienteering Problems. Thanks to Dr. Claudia Archetti and Professor Speranza for patiently answering my questions concerning the data files.

Thanks to all my friends, both at UMCP and everywhere, who have been a great support.

Soli Deo Gloria

List of Figures

2.1 The optimal TSP tour compared with the optimal CETSP tour. The CETSP tour is shorter. 8

2.2 Three representative points are shown, one for each disk. 14

2.3 The two lines connect representative points for nodes i and j. . 16

2.4 The lower bound for both problems is the same. The optimal objective function values are much different. 18

2.5 The shaded region is a Steiner Zone of degree 3 with base node i and is denoted $SZ(3)$. $SZ(3)$ is the intersection of the three disks. 20

2.6 The base node is i. Only the lower (343°) and upper (8°) angles of intersection are required to specify the $SZ(3)$ formed by $disk(i)$, $disk(j)$, and $disk(k)$. 21

2.7 The Steiner zones have degree 2 in both cases. 22

2.8 The nodes are the same in (a) and (b), but the radius is larger in (b). The larger the overlap ratio, the greater the potential savings. 23

2.9 The number of sub-Steiner zones to look through for each new $SZ(k)$ grows roughly exponentially with k. 24

2.10 A 200-node CETSP instance (team2_200) with the optimal TSP solution shown (tour length is about 1074). 25

2.11 team2_200 after applying Phase I. The 200 nodes have been reduced to 16 Steiner zones. 26

2.12 The base node for this Steiner zone is node i. The boundary of $disk(j)$ has at most two points of intersection with the boundary of $disk(i)$. The representative point is the midpoint of the chord that connects the two points of intersection. 28

2.13 team2_200 after applying Phase II. The tour length is about 435. 29

2.14 The solution to team2_200 after applying Phase III. The final tour length is about 304. 29

2.15 Solutions produced by the two GTSP-based heuristics for a 500-node CETSP. 32

3.1 The optimal VRP solution compared to optimal CEVRP solutions. Both CEVRP solutions are shorter. 46
3.2 Three representative points are shown as small black circles, one for each disk. 49
3.3 The two lines connect representative points for nodes i and j. . 53
3.4 The shaded region is a Steiner zone of degree 3 with base node i and is denoted $SZ(3)$. $SZ(3)$ is the intersection of three disks. 54
3.5 The Steiner zones have degree 2 in both cases. 54
3.6 Node i is the base node. Only the lower (343°) and upper (8°) angles of intersection are required to specify the $SZ(3)$ formed by $disk(i)$, $disk(j)$, and $disk(k)$. 55
3.7 The nodes are the same in (a) and (b), but the radius is larger in (b). The larger the overlap ratio, the greater the potential savings. 56
3.8 200-node CEVRP and a near-optimal VRP solution. 58
3.9 200-node CEVRP after Phase I. There are 40 Steiner zones. . . 58
3.10 200-node CEVRP after Phase II. The total length is about 1176. 59
3.11 200-node CEVRP after Phase III. The total length is about 1131. 61

4.1 The optimal TSP tour compared with the optimal CETSP tour. The CETSP tour is shorter. 75
4.2 The shaded region is a Steiner Zone of degree 3 and is denoted $SZ(3)$. It is the intersection of three disks. 76
4.3 The GTSP tour must visit one of the $k = 18$ points in each cluster (circle). 77
4.4 A $k = 24$ GTSP approximation of a 100-node CETSP and the solution found by the GA (about 311). 78
4.5 Two different solutions to the 2D, fixed-radius, Euclidean norm team2_200 problem. The GA's solution has many more Steiner zones than the SZH solution. Consequently, the average Steiner zone degree is much lower for the GA solution than the Steiner-zone solution. 82
4.6 An illustration of better results using more Steiner zones. The depot is at the bottom right. 85
4.7 Elevation map for a 100-node CETSP. Overlap ratio is 0.08 (moderately low). 87
4.8 The base node is i. Only the lower (343°) and upper (8°) angles of intersection are required to specify the $SZ(3)$ formed by $disk(i)$, $disk(j)$, and $disk(k)$. 89

4.9 The total angle of intersection between node i and node k is 95°. SZ_{ik} is created. The total angle of intersection between node i and node j is $< 50°$. SZ_{ij} is not created. 90
4.10 A nearly square route. It is a simple shape and should have a low turn angle. Without accounting for each edge's relative contribution to the tour length, however, the turn angle is very large. 92
4.11 The Steiner zone in Figure 4.11(a) has degree 6. Remove one member node and create a duple with the closest of the other five member nodes. Set the duple aside. 93
4.12 A Steiner zone of degree 4 remains. Remove another node, create a duple in the same manner, and set it aside. 93
4.13 A duple is all that remains. Every third replacement, no matter the number of member nodes remaining, we automatically create a singleton. Set the singleton aside. 94
4.14 Only a singleton remains, so Phase IV for the original $SZ(6)$ is complete, having replaced one high-degree SZ with four low-degree ones. SZH now has more flexibility (a larger solution space) in which to find a good tour on these low-degree Steiner zones. 94
4.15 Solutions to a 200-node CETSP. The GA solution (249.9) is 11% shorter than the Steiner-zone solution (277.6) and has a simpler geometric shape. The SZ solution shape is not simple because the small, high-degree Steiner zones created in Phase I constrain the shape. 96
4.16 Solutions to a 400-node CETSP. The GA solution (680.0) is 9% shorter than the best Steiner-zone solution (742.8). It is difficult to visually judge which route has the simpler geometric shape, but the GA solution has a lower route turn angle. 96
4.17 The route in (a) is about 284 and is not the best Phase III solution to this 200-node problem. After applying Phase IV, the shape is very similar to the GA solution in Figure 4.15(a). The tour length is about 250, only 0.11% longer than the GA solution. 97
4.18 The route in (a) is about 747 and is not the best Phase III solution to this 400-node problem. After applying Phase IV, many of the corners have been smoothed out and the distance is now about 688. This is only 1.27% longer than the GA solution. 98
4.19 Letting ang_{LB} equal each of the integer values in [50°, 59°] produces the best set of solutions, on average, for SZ1_{0-360}, SZ2_{0-360}, and SZ3_{0-360} across all Euclidean problems. 100

5.1 More vehicles do not necessarily produce better objective function values. The triangle is the depot. Edges departing the depot are thicker than others. Edges returning to the depot are not shown. 121
5.2 Solution to a 199-node SDTOP in which 181 nodes are visited by 20 vehicles (route 21 contains all unvisited nodes). 150
5.3 Meta-route for the solution in Figure 5.2. 151

B.1 The two large spheres form a $SZ(2)$ (the small sphere is the depot). $3D_{AN}$ chooses an infeasible representative point. 191
B.2 Two spheric sections 193
B.3 A $SZ(3)$ exists in both figures. 195
B.4 A four-sided spherical polygon (the four great circles are produced by four (hidden) spheres intersecting the visible sphere). 196
B.5 All spheres are shown at 10% opacity. 198
B.6 All spheres are shown at 20% opacity. 198
B.7 2D representation of the Steiner zones drawn in 3D. 199
B.8 Six longitudinal lines represent each SZ. 200
B.9 18 longitudinal lines represent each SZ. 200
B.10 36 longitudinal lines represent each SZ. 201
B.11 60 longitudinal lines represent each SZ. 201
B.12 180 longitudinal lines represent each SZ. 202
B.13 $\alpha = 5$ 203
B.14 $\alpha = 15$ 204
B.15 $\alpha = 30$ 204
B.16 $\alpha = 50$ 205
B.17 A close-up of two Steiner zones when $\alpha = 50$ 205

C.1 $disk(i)$ contains $disk(j)$. $disk(j)$ intersects the $SZ(3)$ based on node i. The boundaries of $disk(i)$ and $disk(j)$ do not intersect, so we cannot calculate upper and lower angles of intersection with $disk(i)$. Without angles of intersection, there is no formula for obtaining a point that is feasible for all four disks although such a point exists. A feasible point would have to be calculated numerically. 228

D.1 Network-flow structure of the IP_{PhIII} model. 261
D.2 The first iteration of the Phase III iterative approximation. . . 262
D.3 Solution after the first two iterations of IP_{PhIII}. 262
D.4 Iteration 3 264
D.5 Iteration 4 265

D.6 Iteration 5 267
D.7 Iteration 6 268
D.8 Iteration 7 269
D.9 Iteration 8 269
D.10 The final result (iteration 30). 270

F.1 An example of trapezoidal decomposition. The dashed vertical lines are called bullet paths. 276
F.2 Two examples of the circular trapezoidal decomposition of a graph of disks. 276
F.3 The base node for this SZ is A. The perimeter of $disk(B)$ has at most two points of intersection with the perimeter of $disk(A)$. The representative point is the midpoint of the chord that connects the two points of intersection. 277
F.4 The lens-shaped region is the intersection of $disk(A), disk(B)$, and $disk(C)$. The intersection of $disk(A)$ and $disk(B)$ lies in the interior of $disk(C)$. Without *a priori* knowledge that either node A or node B is the origin of this zone, we cannot compute a feasible representative point using standard Phase II methods. 278

G.1 The optimal TSP solution and the best known solution for a 300-node CETSP with arbitrary radius. 292

Chapter 1

Introduction

In this dissertation, we model and solve three interesting problems in combinatorial optimization: the Close-Enough Traveling Salesman Problem (CETSP), the Close-Enough Vehicle Routing Problem (CEVRP), and the Sequence-Dependent Team Orienteering Problem (SDTOP). We combine exact techniques (linear, mixed integer, and nonlinear programming) and heuristic methods (greedy search, genetic algorithms, record-to-record travel) to develop efficient heuristic procedures that obtain high-quality solutions to each problem.

1.1 Outline

The Close-Enough Traveling Salesman Problem (CETSP) is a variant of the Traveling Salesman Problem (TSP). In the symmetric TSP, we are given a complete, undirected graph $G = (V, E)$, where V is the set of n nodes (cities), E is the set of edges, and each edge has a length (distance). We need to find the tour (Hamiltonian cycle) that minimizes the sum of the lengths of the edges. In the CETSP, the tour must pass within a specified distance of each node. That is, the salesman must get "close-enough" to each node to visit it.

The CETSP has practical application in unmanned aerial vehicle (UAV) operations, including aerial reconnaissance and delivering munitions to targets. For

instance, if a UAV is carrying a sensor that looks straight down, then the area visible to the sensor will be disk-shaped. As long as the UAV gets close-enough to a target so that the target lies within the sensor's visibility disk, the target can be considered visited. Similar applications exist in submarine reconnaissance of coastlines.

We formulate the CETSP as a nonconvex, mixed integer, nonlinear program (MINLP) and develop lower bounds. The CETSP is at least as difficult as the TSP, which is NP-hard, and, therefore, cannot easily be solved to optimality. A few heuristics for solving the CETSP have appeared recently in the operations research literature [43, 27, 73]. We develop a fast, three-phase solution procedure for the CETSP, called the Steiner-zone Heuristic (SZH). SZH is based on intersections of k disks called Steiner zones. There are no published benchmark problems so we generate 48 test problems with 17 to 1001 nodes. We apply two variants of our heuristic to the benchmark problems and compare the results to those produced by 13 methods. Our heuristic provides the best combination of accuracy and computational speed over all 48 problems.

The Close-Enough Vehicle Routing Problem (CEVRP) is a variant of the Vehicle Routing Problem (VRP). The CEVRP is a multi-vehicle extension of the CETSP. Given a complete, undirected graph $G = (V, E)$, where V is the set of n nodes (cities), E is the set of edges, and each edge has a length (distance), and k homogeneous vehicles, we need to find the set of k tours (Hamiltonian cycles) that minimizes the total sum of edge lengths. There is only one depot. Each node has a demand that must be serviced by exactly one vehicle. Each vehicle is subject to capacity (data storage or payload) and maximum tour length restrictions. A vehicle

must pass within a specified distance of a node to visit it. All n nodes must be visited.

The CEVRP has practical application in UAV operations. The military continues to rely more and more on UAVs to provide timely intelligence and to keep human pilots out of harm's way. Fleets of UAVs can visit many more targets in a given time period than a single aircraft. To use multiple aircraft efficiently, we must solve problems such as the CEVRP.

The CEVRP is a new problem in the operations research literature. We formulate the CEVRP as a nonconvex MINLP. The CEVRP is at least as difficult as the VRP, which is NP-hard, and, therefore, cannot easily be solved to optimality. We extend our Steiner-zone heuristic for the CETSP to solve the CEVRP, replacing the TSP solver with a VRP solver (additional minor changes are also made). We modify the 48 CETSP benchmark problems, adding node demands and vehicles, to create a set of 48 benchmark problems for the CEVRP. We apply four variants of the Steiner-zone heuristic to the benchmark problems and compare the results to the results produced by five heuristics. Two Steiner-zone variants produce the best combination of accuracy and computation speed over all 48 problems.

In the Generalized Traveling Salesman Problem (GTSP) variant of the TSP, n nodes are divided into k clusters. A salesman must visit exactly one node from each cluster. We approximate the boundary of each disk in the CETSP with k points, letting each set of k points form a cluster. We use a genetic algorithm (GA) to solve a GTSP on the k clusters and obtain a feasible solution to the CETSP. For problems where there is only a small or moderate amount of disk overlap (disk overlap creates

the Steiner zones), this GTSP solution procedure consistently produces tours that are shorter than tours produced by SZH. However, the GA is very slow, taking weeks and months to solve larger problems.

We find that the tours produced by the GA are different than the tours produced by SZH. Typically, the GA's tours have a simpler shape. For instance, a solution produced by the GA may have a square shape whereas the comparable SZH tour zigzags from point to point. We develop a post-processor for the Steiner-zone heuristic that tries to improve the quality of its solutions by encouraging a tour with a simpler shape. We show that our post-processor increases the accuracy of the Steiner-zone heuristic substantially with only a very modest increase in computing time.

The Sequence-Dependent Team Orienteering Problem (SDTOP) is a new variant of the Team Orienteering Problem (TOP). In the TOP, a reward, p_i, is given if node i is visited, and a team of k vehicles visits a subset of the n nodes in order to maximize the total reward. In the Sequence-Dependent Team Orienteering Problem (SDTOP), the rewards for visiting nodes are replaced by a matrix, P, whose components p_{ij} give the reward for visiting node i before j. The total profit associated with visiting node i is dependent upon the order in which the nodes are visited (not only for the other nodes in the same route as i but all visited nodes).

The SDTOP can be applied to route a fleet of UAVs on a set of predetermined targets. A real-world UAV routing problem must consider many variables such as wind speed, obstacles to be avoided, aircraft survivability, revisiting targets for re-imaging, requiring certain nodes to be visited before others, wide-area search over

a region, and cooperative control of multiple aircraft. Most papers in the literature consider very limited versions of this problem. For example, some formulations assign priority to each node (similar to p_i in the TOP) and the objective seeks to maximize the total sum of priorities [54, 56, 58, 59, 63, 64]. We suggest that assigning node i a priority (reward) without considering which nodes are visited before and which are visited after i does not fully capture the value relationship between targets. That is, visiting target i before target j may provide a different benefit than visiting j before i. Rather than ignoring the sequence in which nodes are visited or explicitly requiring a specified sequence, we let the objective function determine the order.

We formulate the SDTOP as a Mixed Integer Program (MIP). We develop a heuristic, based on the record-to-record travel procedure, that is capable of solving problems with heterogeneous fleets. Because the evaluation of any new route involves summing the rewards (an $O(n^2)$ operation), p_{ij}, we evaluate the objective function as efficiently as possible. We modify 130 TOP problems from the literature [6] to create benchmark problems for the SDTOP. We compare our solutions to the solutions that are generated when the SDTOP is solved as a VRP (minimizing distance without regard to reward). We create an additional 11 problems in which one of k available vehicles has arbitrarily large capacity and maximum tour length. In this case, the SDTOP reduces to the Linear Ordering Problem (LOP). Provably near-optimal solutions can be found for the LOP [18]. We compare our heuristic's performance on the 11 problems to the near-optimal solutions found by the LOP solver developed by Charon and Hudry [18]. These problems provide evidence that

our heuristic produces high-quality solutions.

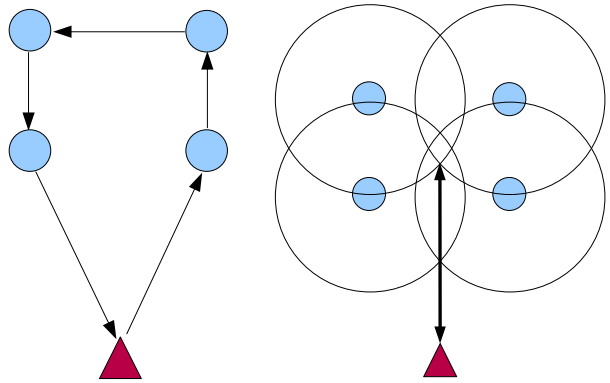
Chapter 2

The Close-Enough Traveling Salesman Problem

2.1 Introduction

The Traveling Salesman Problem (TSP) is one of the most studied problems in operations research. A salesman starts and ends at the same city and must find the cheapest way to visit n cities exactly once. Given a complete, undirected graph $G = (V, E)$, where V is the set of n nodes (cities), E is the set of edges, and each edge has a length (distance), we must find the tour (Hamiltonian cycle) that minimizes the sum of the lengths of the edges in the symmetric TSP. The book by Applegate et al. [13] provides a detailed history of the TSP including applications and computational aspects.

In this chapter, we examine the following variant of the TSP. If a salesman is within a specified distance of a node (in other words, a salesman is "close enough"), then the node is considered to have been visited. We illustrate the CETSP in Figure 2.1. In the standard TSP shown in Figure 2.1(a), the salesman leaves home (the start node is depicted by a triangle), visits four nodes, and returns home. In the CETSP shown in Figure 2.1(b), the salesman needs to get within distance r of each node i (this is depicted by the four disks), where r is the same for each node. If the salesman visits a location in the intersection of the four disks, then each node has been visited. Clearly, the out-and-back solution to the CETSP has a shorter total



(a) TSP tour (b) CETSP tour

Figure 2.1: The optimal TSP tour compared with the optimal CETSP tour. The CETSP tour is shorter.

length than the solution with five edges required by the TSP.

The CETSP has a number of practical applications. Consider the deployment of a drone aircraft (unmanned aerial vehicle) to monitor several geographic regions. To collect its reconnaissance information, the aircraft needs to fly within a certain distance of each region's center. The aircraft has a fixed flying time so that a flight path (tour) must be followed that gets close enough to the center of each region and minimizes flying time (distance traveled).

Utility companies use automated meter reading with radio frequency identification (RFID) to read utility meters from a distance. A meter reader can record the use of water, gas, or electricity within 500 to 1000 feet of a customer and does not need to traverse every street in a neighborhood. The radius of RFID coverage transforms the traditional meter reading problem from a TSP to a CETSP.

In remainder of this chapter, we review the literature on the CETSP (Section 5.2) and formulate this problem as a mathematical program (Section B.1). We develop a solution method based on Steiner zones (Section 5.5), generate a set of test

problems, and conduct extensive computational experiments in which we compare the results of our method to the results of other methods, including a genetic algorithm, a tour generation and modification heuristic, and a greedy heuristic (Section 3.5).

2.2 Literature Review

The CETSP is a specific case of three well-known combinatorial optimization problems: the Covering Tour Problem (CTP), the TSP with Neighborhoods (TSPN), and the Generalized TSP (GTSP).

In the CTP, there is a discrete set of nodes, V, that can be visited, a set of nodes, $T \subseteq V$, that must be visited, and a set of nodes, W, that must be covered. To be covered, node i must lie within a specified distance of a node in the tour. A continuous version of the CTP is the Geometric Covering Salesman Problem (GCSP) where V consists of entire regions in the plane [8]. For the CETSP, $T = \emptyset$, V is the set of all points on the boundaries of the disks, and W is the set of n nodes. Arkin and Hassin [8] and Current and Schilling [23, 24] present worst-case performance bounds for the CTP for various types of regions, including parallel line segments and disks. Gendreau et al. [37] present a branch-and-cut algorithm and a heuristic for the CTP. They suggest aerial forest-fire detection as a possible application for the CTP.

In the GTSP, each of the n nodes is assigned to one of k clusters. The clusters have arbitrary size and are not necessarily disjoint. A feasible solution tour visits

exactly one point (some definitions specify at least one point) in each cluster. In the CETSP, the boundary of each node's disk can be considered a cluster with an infinite number of points. Solving the GTSP over a discrete subset of these perimeter points for each disk produces a feasible solution to the CETSP. Fischetti and Toth [36] present polyhedral results along with a branch-and-cut algorithm for the exact solution to the GTSP. Recently, Silberholz and Golden [67] describe a genetic algorithm (GA) that found new best solutions for many of the standard test problems.

In the TSPN, each customer (node) is willing to travel a distance in a neighborhood to meet the salesman. The neighborhood may be a straight line, convex polygon, disk, or a general, non-convex region. De Berg et al. [25], Safra and Schwartz [61], Dumitrescu and Mitchell [31], Mitchell [52, 53], Gudmundsson and Levcopoulos [42], Arkin and Hassin [7], and Elbassioni [32, 34, 33], have studied approximation algorithms with provable worst-case bounds for different versions of the TSPN, including one where the regions are disjoint unit disks. Mitchell [53] presents the first known polynomial time approximation scheme (PTAS) for the TSPN where every region is only required to be fat. A c-fat region, P, contains a circle of diameter at least $c^{-1} * diameter(P))$ for some constant c. A circle is therefore 1-fat since it contains itself. In [53], regions are simply described as fat, implying that some constant, c, exists but need not be explicitly stated.). Elbassioni et al. [33] give the tightest known upper bounds for the TSPN for continuous, convex regions. Their bounds are dependent on the fatness of the regions. There are no known worst-case bounds for the TSPN where the regions are fat, convex, of varying

size, continuous, and possibly intersecting. Thus, there is no known algorithm with worst-case bounds for the CETSP. We note that none of the algorithms proposed in the literature is designed to produce high-quality solutions quickly. They only guarantee worst-case bounds on performance.

Klesh [49] studies time-optimal aerial exploration of a given region for autonomous aircraft. Objects of interest, such as radar sites, are visible to the aircraft only when the aircraft is within the object's *visibility disk*, a disk of a specified radius. Unlike the CETSP, flight paths are not straight-line edges between nodes and aircraft cannot turn instantaneously. Klesh develops necessary conditions for optimal flight path planning with multiple (possibly intersecting) disks and a single vehicle. He describes two methods, a rubberband heuristic and a GTSP-based heuristic, for solving this problem but does not report any test results.

The first description of the CETSP, specifically, is given by Gulczynski, Heath, and Price [43]. They consider utility companies that use RFID to read meters from a distance. The authors present six heuristics (three variants of tiling, radial adjacency, sweeping circle, Steiner zone) for solving problems with Euclidean distances and r is the same for all disks. The heuristics were developed by teams of graduate students as part of a class project. The six heuristics have three steps in common.

- Step 1. Find a feasible supernode set S such that each customer i is within r units of at least one point in S.
- Step 2. Solve a TSP on the points in S to produce a near-optimal solution T that is a feasible solution to the CETSP.

- Step 3. Reduce the distance traveled in T while maintaining feasibility.

Each heuristic has a different approach to finding S in the first step. Three heuristics use variations of hexagonal tiling in which the plane is tiled with regular hexagons. Feasibility is ensured since the center of each hexagon is no more than r units from any node inside the hexagon. The radial adjacency heuristic uses a binary matrix to build supernodes. A value in the matrix is 1 if two nodes are within distance r from each other and 0 otherwise. The sweeping circle heuristic covers the plane with supernodes that are circles instead of hexagons. The circles are merged into a set of supernodes that cover all original nodes. The Steiner-zone heuristic, an earlier implementation of the work presented here, constructs the supernodes (Steiner zones) by examining points that lie in the intersections of multiple circles (more about this in Section 5.5). The six heuristics were applied to seven test problems with 101 to 1001 customers. In this limited computational experiment, the tiling heuristic that merged supernodes and the Steiner-zone heuristic produced high-quality results.

Dong, Yang, and Chen [27] formulate the CETSP as a mixed integer, nonlinear program (MINLP), but they do not attempt to solve it. Instead, they develop two heuristics that use clustering (merged tiling) or convex hulls to generate the supernodes. The TSP tour over the supernodes is constructed with a convex hull insertion algorithm. The tour is improved with a simulated annealing algorithm. The authors test their two heuristics on 190 random Euclidean problems with 100 to 1000 customers and 10 different radii. Both heuristics produced good solutions

and were very fast with running times under one second.

Yuan, Orlowska, and Sadiq [73] consider the problem of routing a mobile robot to visit sensors that are distributed in the Euclidean plane. In order to communicate with a sensor and download data, a robot must be within a certain distance of it (the effective range is specified by a disk and the disks do not overlap). The authors develop an evolutionary approach for solving the robot routing problem and compare its performance to an approximation algorithm on five problems with 19 to 300 sensors. The evolutionary approach generated the shortest tour for each problem although the convergence speed was slow.

Shuttleworth et al. [65] extend the CETSP to street networks. They consider a real-world meter reading problem that uses actual data. The authors solve the problem using a two-stage process. In the first stage, a heuristic selects a subset of street segments to be traversed based on the radius r. In the second stage, street segments are added to the subset of street segments from the first stage to form a cycle. Shuttleworth et al. [65] consider four simple heuristics and two integer programs for selecting the street segments. For example, the weighted bang-for-buck heuristic first selects the street segment that covers the largest number of customers, then selects the street segment that covers the largest number of additional customers, and so on until each customer is covered by at least one street segment. The authors use a commercial vehicle routing system (RouteSmart's sequence solver) to produce a complete travel path that starts and ends at the depot. Computational results showed that the weighted bang-for-buck heuristic was simple and effective, and generated solutions that saved time and distance when compared

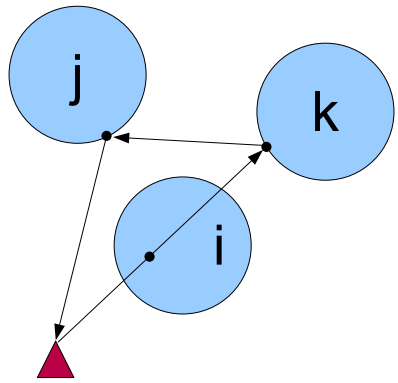


Figure 2.2: Three representative points are shown, one for each disk.

to the existing route used by the utility company.

2.3 Formulation

In this section, we formulate the CETSP as a MINLP. In the CETSP, a tour must cross a disk of radius r surrounding every node as shown in Figure 3.2. We refer to the disk surrounding node i as $disk(i)$. Any tour that touches or passes through $disk(i)$ successfully visits node i (with the exception of the depot (node 0) which has no disk). Node i is a fixed point in the plane at coordinate (a_i, b_i). We denote (a_i, b_i) as $orig(i)$, the origin of $disk(i)$, to emphasize that each node is surrounded by a disk. We assume that $orig(i) \neq orig(j)$ for all i and $j \geq 0$. The depot, however, may have the same coordinates as node i. Let ϵ be the smallest length of any edge. Requiring all edges to have non-zero length does not eliminate feasible solutions when the depot has the same coordinates as node i as long as ϵ is sufficiently close to zero.

Let (x_i, y_i) be the coordinate on the tour that is close enough to node i.

Coordinate (x_i, y_i) is known as node i's *representative point*. x_i and y_i are both unbounded continuous variables. In Figure 3.2, we illustrate the concept of representative points. Any of the points on the line through $disk(i)$ can be selected as node i's representative point. Distances in the CETSP are given by $\sqrt{(x_i - x_j)^2 + (y_i - y_j)^2}$. Let e_{ij} be a binary variable equal to 1 if node i immediately precedes node j on a tour and 0 otherwise. Our mixed-integer, nonlinear formulation of the CETSP is given below.

$$\text{Minimize} \quad \sum_{i=0}^{n} \sum_{j=0}^{n} e_{ij} \sqrt{(x_i - x_j)^2 + (y_i - y_j)^2} \tag{2.1}$$

subject to

$$(x_i - a_i)^2 + (y_i - b_i)^2 \leq r^2 \qquad i = 1, \ldots, n \tag{2.2}$$

$$\sum_{i=0}^{n} e_{ij} = 1 \qquad i, j = 0, \ldots, n \tag{2.3}$$

$$\sum_{j=0}^{n} e_{ij} = 1 \qquad i, j = 0, \ldots, n \tag{2.4}$$

$$\sum_{i,j \in S} e_{ij} \leq |S| - 1 \quad \text{for } S \subseteq \{1, \ldots, n\},\ 2 \leq |S| \leq n \tag{2.5}$$

$$\sqrt{(x_i - x_j)^2 + (y_i - y_j)^2} \geq \epsilon \qquad i, j = 0, \ldots, n \tag{2.6}$$

$$e_{ij} \in \{0, 1\},\ (x_i, y_i) \in R \times R \qquad i, j = 0, \ldots, n \tag{2.7}$$

The objective function (2.1) minimizes the distance of the tour. However, the distance coefficients are not constants. The coefficients are functions of the representative points. In Figure 3.3, we show how different choices of representative points affect the edge distance between node i and node j.

Constraint (2.2) requires each representative point i to lie within a disk arround

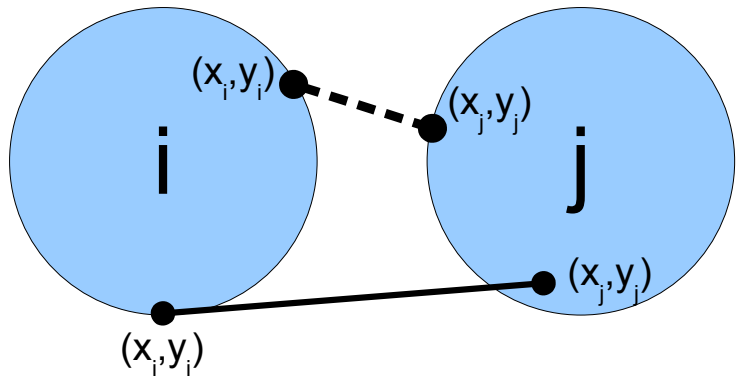

Figure 2.3: The two lines connect representative points for nodes i and j.

(a_i, b_i). Note that this constraint's index does not include the depot ($i = 0$) as there is no disk around the depot. Constraints (2.3) and (2.4) are assignment constraints that require each node to be visited exactly once. Constraint (2.5) prohibits subtours by forcing the number of edges in any subset of the non-depot nodes to be at most one less than the subset's cardinality. Constraint (2.6) requires the distance between any two representative points to be strictly positive. Without (2.6), edges in the tour can have length 0. If k disks have the same representative point, all $\binom{k}{2}$ edges between the k disks have length 0 and could be selected without increasing the objective function value. Assignment constraints ensure that exactly one edge enters and one edge exits each node. However, without (2.6), a node can have multiple predecessors and successors. In preliminary experiments, a solver was unable to find a feasible solution for very small problems where zero-length edges are possible. When constraint (2.6) is included, zero-length edges cannot occur and the assignment constraints ensure a single predecessor and successor for each node. Consider the problem in Figure 2.1(b) where each disk has the same representative point. If this problem is solved

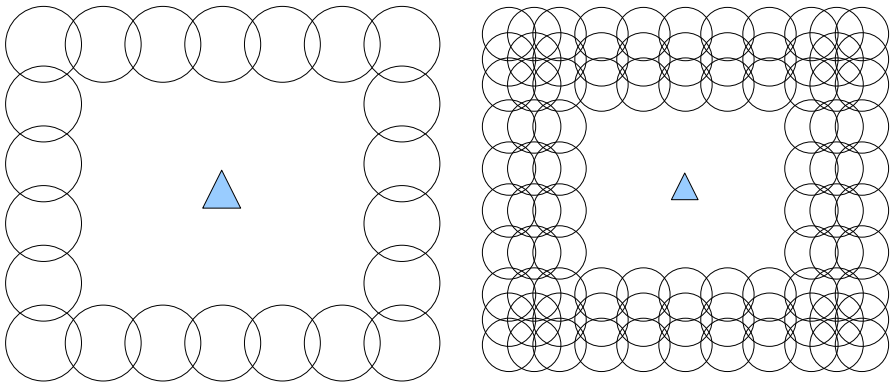
using the formulation including constraint (2.6), the single representative point is replaced by four points ϵ units apart. For values of ϵ sufficiently close to zero, our formulation produces the same optimal routes as if we could solve with $\epsilon = 0$. We point out that in (2.7), x_i and y_i are free variables. Their bounds (staying in $disk(i)$) are enforced by constraint (2.2). In addition, the CETSP reduces to the TSP when $r = 0$.

2.3.1 Lower Bounds

The CETSP is a non-convex MINLP. We cannot apply the standard 1-tree and 2-matching lower bounds techniques for TSPs without significant modifications. We construct a lower bound in the following way. Let $\bar{d}_{ij} = \min(0,\ d_{ij} - r)$ when either i or j is the depot. Otherwise, $\bar{d}_{ij} = \min(0,\ d_{ij} - 2r)$. If disks i and j overlap, then $\bar{d}_{ij} = 0$. We fix each edge in G to its minimum possible distance and solve a TSP to optimality using the set of all $\bar{d}_{ij}$. In Figure 2.4, we show two problems that differ in size and optimal CETSP solution but have the same lower bound using our method. Each layer of squares overlaps the next one so that $\bar{d}_{ij} = 0$ for all overlapping disks. The lengths of the optimal tour are the same for both problems.

Clearly, this lower bound is weak. When there is medium to high disk overlap, the lower bound is close to zero while the best tour is hundreds of units above zero. Unless there is no disk overlap and r is small, the lower bound provides no information about the optimality gap, as shown in Table 2.3.1.

Another lower bound technique is the longest out-and-back tour from the depot



(a) 22-node problem (b) 90-node problem

Figure 2.4: The lower bound for both problems is the same. The optimal objective function values are much different.

to any node. A CETSP cannot have an optimal solution shorter than the straight line out to the boundary of the disk furthest from the depot and back. This bound is also very weak.

2.4 Heuristic

Let $SZ(k)$ denote a Steiner zone of degree k. A $SZ(k)$ is the non-empty intersection of k convex regions. In this case, the regions are disks. Any point in $SZ(k)$ is close enough to all k member nodes, as shown in Figure 4.2. A Steiner zone of degree 1, $SZ(1)$, is called a *singleton*. We denote the origin of one of the k nodes whose disks form a $SZ(k)$, say node i, as the *base node* for the $SZ(k)$. For example, node i is the base node for the $SZ(k)$ in Figure 4.2. Since a point in a Steiner zone is not in general one of the original nodes to be visited and yet a visit to this point may reduce the total length, we envision these zones affecting the TSP as Steiner points affect the minimal spanning tree problem. The name Steiner zone comes from this observation.

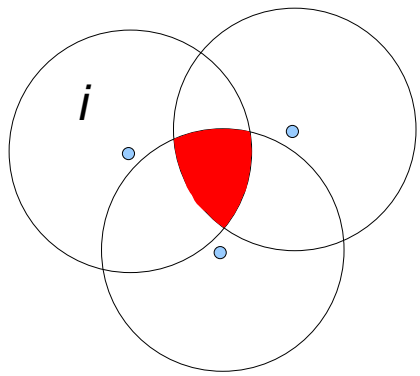

Figure 2.5: The shaded region is a Steiner Zone of degree 3 with base node i and is denoted $SZ(3)$. $SZ(3)$ is the intersection of the three disks.

A $SZ(k)$ with base node i is characterized by two polar angles, relative to $orig(i)$, with which the other $k-1$ disks intersect $disk(i)$, and the origins of the $k-1$ disks. The two angles are called upper and lower angles of intersection and are easily generated. For $k \geq 3$, the angles of intersection are obtained by comparing the angles of intersection for two Steiner zones with base node i, a $SZ(k-1)$ and a $SZ(2)$. If the angles overlap, then the upper and lower angles of that overlap become the upper and lower angles of intersection for the $SZ(k)$. For example, in Figure 4.8, the $SZ(2)$ formed by $disk(i)$ and $disk(j)$, with base node i, has lower and upper angles of intersection of 343° and 55°, respectively. The $SZ(2)$ formed by $disk(i)$ and $disk(k)$, with base node i, has lower and upper angles of intersection of 299° and 8°, respectively. The two sets of angles overlap such that the $SZ(3)$ formed by $disk(i)$, $disk(j)$, and $disk(k)$, with base node i, has a lower angle of intersection of 343° and an upper angle of intersection of 8°. When two or more disks intersect at exactly one point, the upper and lower angles of intersection are equal. As long as we know the base node and the upper and lower angles of intersection, we can

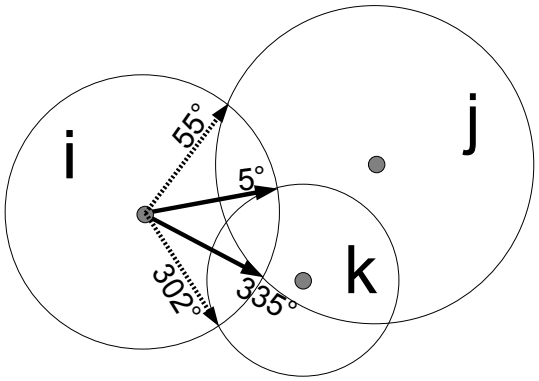

Figure 2.6: The base node is i. Only the lower (343°) and upper (8°) angles of intersection are required to specify the $SZ(3)$ formed by $disk(i)$, $disk(j)$, and $disk(k)$.

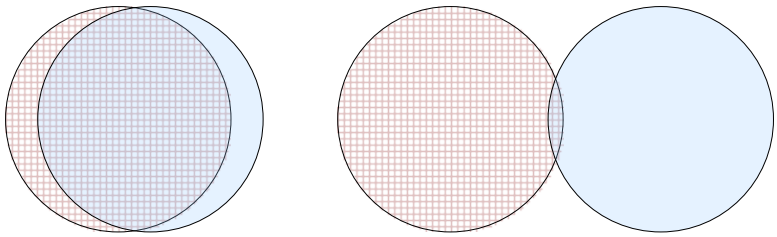
easily generate a point within r of each $disk(i)$ within a $SZ(k)$. In Figure 3.5, we show two Steiner zones of equal degree with different size overlaps.

In Figure 3.7, we see that the larger the radius, the larger the potential savings in tour length. For example, if r is very large, we can expect a much shorter optimal CETSP tour than the optimal TSP tour. If r is near zero, the optimal CETSP result will be only slightly shorter than the optimal TSP solution. We define a metric, *overlap ratio*, to indicate how much potential there is for improvement over the TSP solution. For a given CETSP, let $l_{contain}$ be the length of a side of the smallest square containing all n disks. The overlap ratio is the ratio of r to $l_{contain}$. In Figure 3.7, we show two different overlap ratios for the same set of nodes. We consider instances with an overlap ratio much larger than 0.3 uninteresting because almost any sequence of n nodes will produce a near-optimal solution to the CETSP. Overlap ratio is not appropriate for problems which lie in an elongated rectangle rather than a square, but it provides an indication of how much improvement is possible.



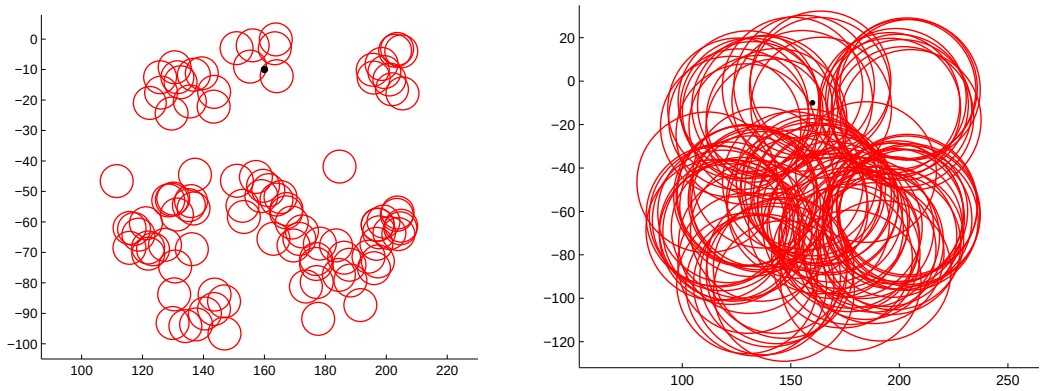
(a) large intersection (b) small intersection

Figure 2.7: The Steiner zones have degree 2 in both cases.

Our Steiner-zone heuristic, denoted by SZH, reduces a graph of n nodes to a graph of m Steiner zones, sequences the m zones, and locates the best representative point for each zone given the tour sequence. Node 0 is the depot and cannot be part of any Steiner zone. We now describe the three phases of SZH in detail.

2.4.1 Phase I - Graph Reduction

We describe two approaches to graph reduction. The first is a slow, naive heuristic. The second approach is a modification of the first heuristic and is faster. We begin by sorting the nodes and storing them in a list, denoted by $list$. We use four different sorts: closest to and furthest from the depot and closest to and furthest from the centroid of the graph. We select the first node in $list$, say i, and identify all Steiner zones that node i can form, storing them in a list called SZ_list_i. To do this, we consider all other nodes and calculate their angles of intersection with i, if possible. Let SZ_{ij} denote the $SZ(2)$ formed between nodes i and j. We compare SZ_{ij} with all previously identified Steiner zones already in SZ_list_i. Whenever SZ_{ij}'s angles of intersection overlap those of a Steiner zone in SZ_list_i, we form a new Steiner zone from their intersection. SZ_list_i is ordered from highest degree



(a) overlap ratio 0.05 (b) overlap ratio 0.2

Figure 2.8: The nodes are the same in (a) and (b), but the radius is larger in (b). The larger the overlap ratio, the greater the potential savings.

to lowest degree. That is, the Steiner zones capturing the intersection of a large number of disks are stored before those describing the intersections of fewer disks. Steiner zones of equal degree are ordered lexicographically. For example, a $SZ(3)$ consisting of nodes 1, 5, and 6 would be ordered prior to a $SZ(3)$ consisting of nodes 1, 6, and 9. With this ordering, we can easily locate a particular Steiner zone in SZ_list_i. To avoid a long search through SZ_list_i, we use bookmarks that store the location of the first Steiner zone in the list of each degree, k, for small values of k.

Consider the following example. We have selected node 1 from *list* and have compared it with nodes 2 through 5, such that SZ_list_1 is: {1,2,3}, {1,2}, {1,3}. Considering node 6 next, we find that nodes 1 and 6 form a $SZ(2)$. The lower and upper angles of intersection are 40° and 130°. We compare these angles against the angles of intersection for the three Steiner zones already in SZ_list_1 and find that {1,6} overlaps {1,2,3}. We have found a new Steiner zone, {1,2,3,6} and must add it to the list along with all sub-Steiner zones associated with it. SZ_list_1 now looks like: {1,2,3,6}, {1,2,3}, {1,2,6}, {1,3,6}, {1,2}, {1,3}, {1,6}. After constructing all

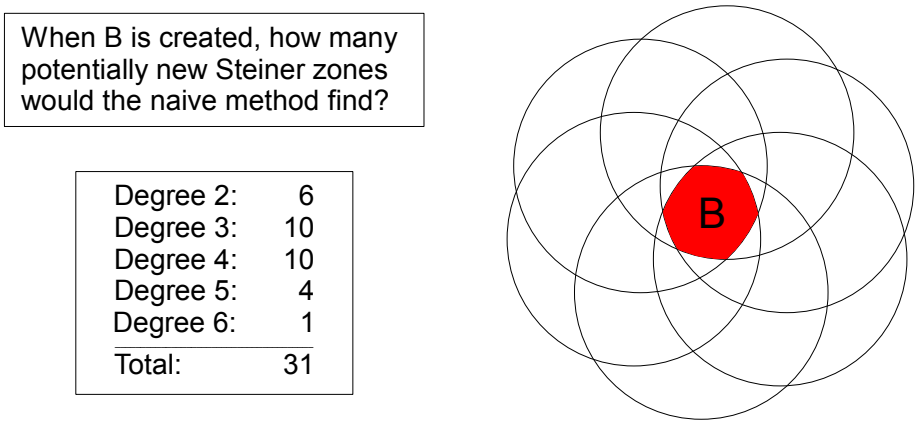


Figure 2.9: The number of sub-Steiner zones to look through for each new $SZ(k)$ grows roughly exponentially with k.

Steiner zones for node i, we set aside the highest degree Steiner zone for later use, and remove its nodes from $list$. This is repeated until $list = \emptyset$. When there are no nodes to consider, a set of Steiner zones remains such that any tour visiting each of these Steiner zones is a feasible solution to the CETSP.

In Figure 2.9, we illustrate the shortcoming of this naive approach to graph reduction. Assume $B = SZ(k)$ is found, where k is an integer larger than three. There is a set of unique sub-Steiner zones of degrees $k-1$, $k-2$, $\ldots$, 2, such that all members of the set contain B and may or may not have been identified yet. Therefore, we must identify all of them individually. As k grows, the number of possible sub-Steiner zones to identify grows exponentially. The vast majority of them, however, are contained in other larger Steiner zones and are thus redundant, creating giant lists of Steiner zones to store and search. Early experiments confirmed that this approach to graph reduction is computationally expensive. Because of the large number of sub-Steiner zones that must be identified, a large amount of

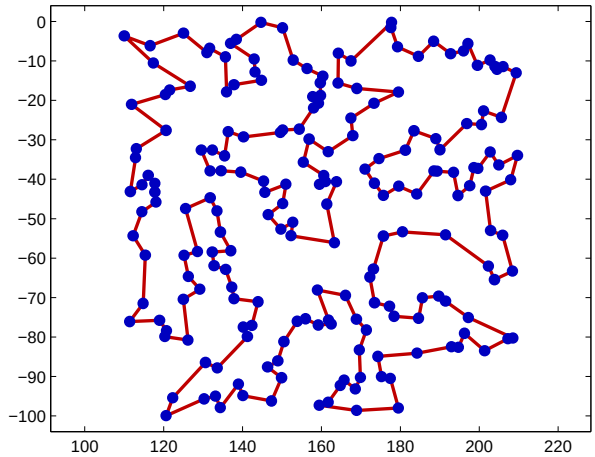

Figure 2.10: A 200-node CETSP instance (team2_200) with the optimal TSP solution shown (tour length is about 1074).

computation time (on the order of days) is needed to find Steiner zones of degree as small as 20.

Our second approach to Phase I differs from the naive heuristic only in its treatment of sub-Steiner zones. In addition to adding B to SZ_list_i, we add only those sub-Steiner zones of B that have degree no greater than three and have not previously been added. In computational experiments, our second approach is very fast (less than a second) and easily identifies Steiner zones with degrees in the thousands. The sub-Steiner zones of degree two and three seem to act as a suitable seedbed upon which to construct the Steiner zones of large degree. The choice of three as a cut-off value is arbitrary. In our experience, using a larger value slows the graph reduction without finding Steiner zones of much higher degree.

In Figure 2.10, we show an optimal TSP tour for a 200-node problem known as team2_200. In Figure 2.11, we show the Steiner zones that result from applying Phase I to team2_200. The Steiner zones happen to be disjoint. However, the Phase

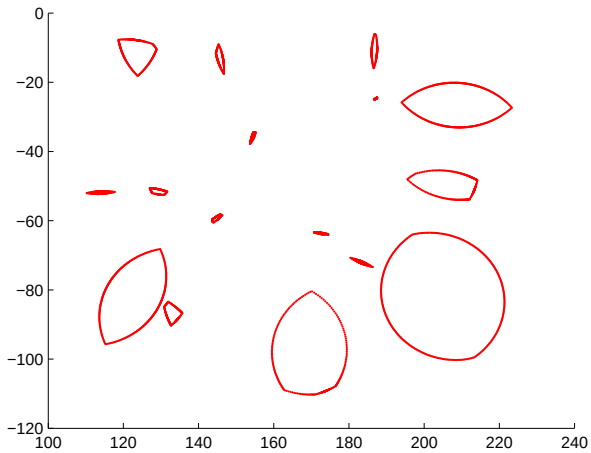

Figure 2.11: team2_200 after applying Phase I. The 200 nodes have been reduced to 16 Steiner zones.

I algorithm does not explicitly require or encourage disjoint Steiner zones.

We incorporate all four sorting criteria (closest-to-depot, furthest-from-depot, closest-to-centroid, furthest-from-centroid) into our heuristic, by solving Phases I - III for each criteria. That is, SZH is actually four different runs of the Phase I - Phase II - Phase III cycle, one run for each of the four orderings. In preliminary experiments, we found that a sorted *list* always produced shorter tours than a randomly ordered *list*.

2.4.2 Phase II - Tour Finding

The result of applying Phase I to graph G is graph G'. G' is a graph of Steiner zones rather than nodes. We designate a point in each Steiner zone as its representative point and solve a TSP on these points.

Given a $SZ(k)$ with base node i and $k \geq 2$, a chord may be drawn connecting the points on $disk(i)$ at the upper and lower angles of intersection. Because the

intersection of convex sets is convex and a $SZ(k)$ is the intersection of k convex sets (disks), any point along this chord (we select the midpoint of the chord) must lie within the $SZ(k)$. We show this in Figure 2.12.

For singletons, we choose the point on the disk's perimeter closest to the depot. A well-known method, such as the Concorde TSP Solver [1, 13], can be used to find the TSP tour on this set of points. The result is a feasible solution for the CETSP. Note that many TSP solvers require integer node coordinates. Our test problems do not have integer coordinates. This obstacle is easy to overcome by multiplying the coordinates by the appropriate power of 10. For example, if all coordinates have two decimal places, such as 123.45, the appropriate scaling factor would be 100, so that all coordinates are integer. If a coordinate has a large number of decimal places, for example 1.946382438, converting it to an integer accurate to all decimal places (1.946382438 becomes 1946382438) could produce numbers too large for the TSP solver to handle. Therefore, for each problem, we determined the smallest power-of-10 scaling factor such that the TSP solution for any feasible, larger power of 10 is the same. In this way, we achieve the most accurate solution possible given the TSP solver's numerical capabilities.

2.4.3 Phase III - Tour Improvement

The result of applying Phase II to G' is a feasible solution to the CETSP. The sequence in which the tour visits the Steiner zones is fixed, but the location of each Steiner zone's representative point can still be modified. In Figure 2.13, we show the

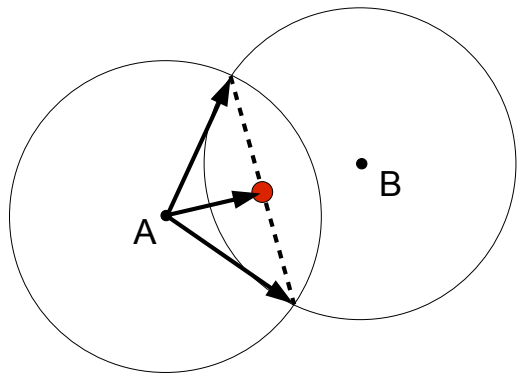

Figure 2.12: The base node for this Steiner zone is node i. The boundary of $disk(j)$ has at most two points of intersection with the boundary of $disk(i)$. The representative point is the midpoint of the chord that connects the two points of intersection.

results after applying Phase II to team2_200. We notice that: (1) the tour length is much less than the tour length of the optimal TSP solution, and (2) the tour could be shortened by changing the placement of representative points for each Steiner zone. To determine the optimal placement of the representative points, we solve the Touring Polygons Problem (TPP) described in Dror et al. [29] where we consider convex regions (Steiner zones) instead of polygons. We call this the Touring Steiner Zones Problem (TSZP). Given a tour on a set of disks, the TSZP minimizes the distance such that each Steiner zone (and thus each disk) remains feasibly covered and the sequence of Steiner zones visited remains unchanged.

We can formulate the TSZP as a second-order cone program (SOCP) and solve it optimally using CPLEX (see Appendix E). Our heuristic approach, denoted IP_{PhIII}, solves a succession of shortest path problems that converge to a near-optimal solution of the TSZP. Phase I, Phase II, and Phase III are equally important in SZH. IP_{PhIII} is complicated so we illustrate it by means of an example in Appendix D. In

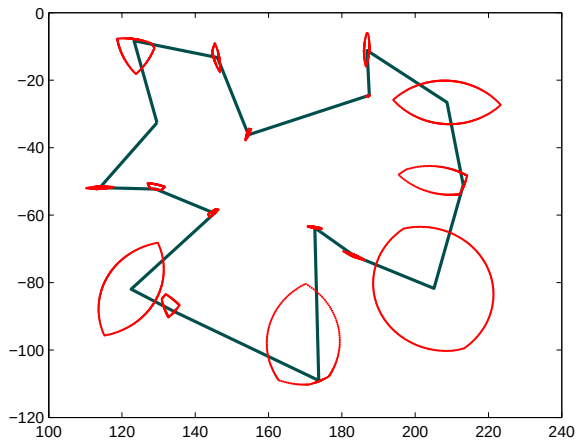

Figure 2.13: team2_200 after applying Phase II. The tour length is about 435.

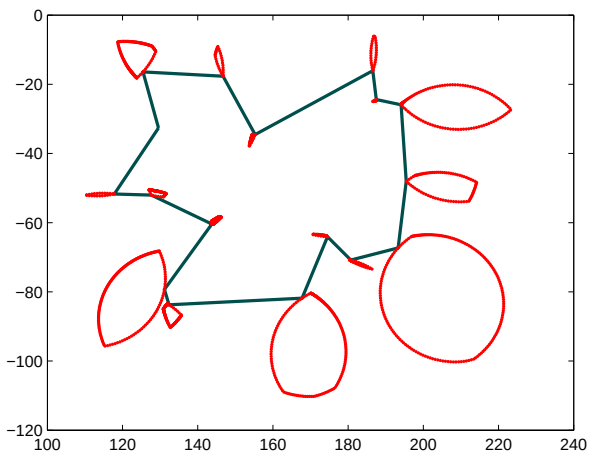

Figure 2.14: The solution to team2_200 after applying Phase III. The final tour length is about 304.

Figure 2.14, we show the solution to team2_200 after applying our heuristic solution to Phase III. In Appendix H, we provide the pseudocode for SZH where Phase III is solved with the IP_{PhIII} heuristic.

2.5 Computational Results

We selected seven TSPs from TSPLIB [4] that ranged in size from 100 to 1000 nodes including the depot. Two problems have clustered nodes, one has nodes arranged in rough lines, two have uniformly distributed nodes, and two are drill-press problems. In order to create CETSPs from the TSPs, we assigned three different radius patterns: (1) the overlap ratio is 0.02 (very low), (2) the overlap ratio is 0.1 (moderate), and (3) the overlap ratio is 0.3 (very high). We refer to these as $TSPLIB$ problems.

In addition to the $TSPLIB$ problems, we created 27 problems with 17 to 1001 nodes including the depot. 20 problems are geometric: nine *Bubbles* problems have concentric squares of overlapping nodes, five *ConcentricCircles* problems have nodes arranged in concentric circles, five *RotatingDiamonds* problems have non-overlapping concentric squares, and $ChaoCEVRP$ is based on a problem given in Chao [15]. The remaining problems are the seven $Team$ problems discussed in Gulczynski et al. [43]. Three of the $Team$ problems have uniformly generated points, and four are clustered [43]. Two of the $Team$ problems have high overlap ratios. The remaining 25 problems have low and medium overlap ratios. We refer to these 27 problems as $GEOMETRIC$ problems. In each of the total of 48 problems, all nodes have equal radius. All problem data are given in Appendix L.

We used the implementation of the Lin-Kernighan heuristic provided in the Concorde software package to solve Phase II. We tried Helsgaun's implementation of Lin-Kernighan [45] and the Concorde exact solver but found no advantage worth

the extra computation time.

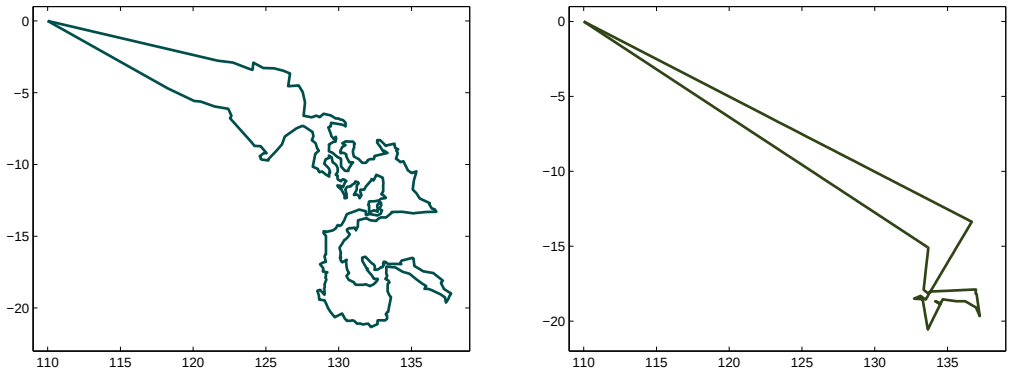
We coded 15 CETSP solution methods for comparison purposes. SZ1 is our Steiner-zone heuristic where we solve Phase III approximately using IP_{PhIII}. After Phase III, we re-run Phase II and stop. We apply IP_{PhIII} only until each Steiner zone is approximated by a 1536-sided polygon. This method emphasizes computational speed over tour length.

SZ2 is the same as SZ1 except that Phase III is solved to optimality using the SOCP formulation and the Phase II - Phase III cycle is repeated until no improvement is found. In computational experiments with problems up to 1001 nodes, this occurs after no more than three iterations of this cycle. This method emphasizes tour length over computational speed.

LK-SOCP does not use Steiner zones. It solves only Phase II and Phase III of our heuristic. That is, it finds a near-optimal TSP sequence on the original nodes (Phase II) and solves the Phase III SOCP formulation to optimality. The Phase II - Phase III cycle is run exactly once.

GTSP1 finds near-optimal solutions to a generalized TSP (GTSP) approximation of the CETSP using a genetic algorithm developed by Silberholz et al. [67].

By replacing each disk with k points, we create a GTSP where there are n clusters to be visited, each with k possible points to choose from. We used 3-, 6-, 12-, and 24-point approximations of each disk. Only the 24-point approximations were competitive, however, so we do not report on the 3-, 6-, and 12-point approximations. Silberholz et al.'s algorithm was an average of only 0.03% from optimality on the standard GTSP test problems of size up to 442 total nodes and found new



(a) GTSP1 (b) GTSP2

Figure 2.15: Solutions produced by the two GTSP-based heuristics for a 500-node CETSP.

best solutions for the larger problems with unknown optimal solutions. Our GTSP problem sizes range from 2,400 nodes to 24,000 nodes plus the depot.

GTSP2 applies the Phase III SOCP tour improvement to the GTSP1 solution. In Figure 2.15, we show the difference between a GTSP1 solution and a GTSP2 solution for the same problem.

HYBRID1 is Phase I of SZH followed by the GTSP genetic algorithm, with each Steiner zone approximated by 24 points. Phase III of the Steiner zone heuristic is applied to the resulting tour, using the IP_{PhIII} heuristic. GTSP and Phase III are applied once. HYBRID2 is the same as HYBRID1 except that, in Phase III, we solve the SOCP formulation using CPLEX.

CTD, circular trapezoidal decomposition, is a modification of the trapezoidal decomposition algorithm of Mulmuley [55]. CTD subdivides a graph of disks into non-overlapping regions such that each region is bordered on the left and right by vertical lines and on the top and bottom by arcs of a disk. Using this subdivision, we compute the degree of all distinct regions in the graph and greedily select the regions

with the highest degree. We then generate Steiner zones from these regions and finish by applying Phase II and the SOCP formulation of Phase III. In computational experiments, computing the subdivision for problems with large overlap ratios is computationally expensive. See Appendix F for more details.

TILE1 uses the shifted tiling method from Gulczynski et al. [43]. The authors provided their code to use in our experiments. Their code uses a genetic algorithm to solve Phase II. To ensure a fair comparison with our heuristics, TILE1 solves Phase II to optimality using the Concorde TSP solver [1]. The degree of the supernodes found by the shifted tiling heuristic depends on a parameter called step-size. TILE1 uses the default setting where step-size is equal to the disk radius.

TILE2 is the same heuristic as TILE1 except that Phase II is solved using the chained Lin-Kernighan code from Concorde [1].

TILE3 solves Phase II to optimality using Concorde and sets step-size to 50 for all problems. This ensures that problems with a small radius spend as much effort finding supernodes as problems with a large radius.

TILE4 is the same heuristic as TILE3 except that Phase II is solved using the chained Lin-Kernighan code from Concorde [1].

YUAN+ is an improved version of the heuristic given in Yuan et al. [73]. The heuristic specified by Yuan et al. does not apply a Phase I method. It finds the optimal TSP tour on the original nodes (Phase II) and applies an evolutionary algorithm to minimize tour distance (Phase III). We modified their algorithm to solve Phase III to optimality for a given tour using the SOCP formulation. This algorithm is the same as LK-SOCP except that Phase II is solved to optimality

rather than approximately.

MERGE is the merged tiling heuristic given in Dong et al. [27]. The authors provided their code (a version optimized for computational speed) to use in our experiments.

HULL is the convex-hull heuristic described in Dong et al. [27]. We used their code in our experiments.

We did not test our heuristic against the heuristic described in Shuttleworth et al. [65]. They solve the CETSP over a street network (the triangle inequality does not hold). None of the algorithms in our experiments were designed to work for the CETSP over a street network.

All experiments were performed on a 2.4 GHz Pentium machine with 3 GB RAM running Windows XP Professional. We note that different computers have different floating-point architectures. Very small numerical differences can add up over a computation and affect the outcome of SZH. Thus, for a small number of problems, we obtained a different solution for the same problem on different computers. All solutions are checked for feasibility. All methods use the same code to solve Phase III. Except for the genetic algorithm and the hybrid heuristics, all solution methods use the same code to solve Phase II. No special attention was given to the Steiner-zone methods to improve performance.

The tour-length results for the 15 heuristics on the 48 problems using the Euclidean norm are given in Table 2.2. The average deviations from the best solutions in Table 2.2 are given in Table 2.3. Columns in both tables are ordered by the overall average deviation from best (left) to worst (right). For Table 2.2, bold font

indicates the best value.

In Table 2.2, for the seven low overlap $TSPLIB$ problems, GTSP2 produces all the shortest tours. For the seven medium overlap $TSPLIB$ problems, GTSP2 produces the shortest tour five times. For the seven high overlap problems, LK-SOCP and YUAN+ each produce the shortest tours four times. GTSP2 produces the shortest tour for 15 $GEOMETRIC$ problems while $HYBRID2$ finds 8 shortest tours.

In Table 2.3, we see that, on average, GTSP2 and GTSP1 produce the smallest deviations (0.00% and 0.55%) for $TSPLIB$ problems with a low overlap ratio. For $TSPLIB$ problems with a medium overlap ratio, GTSP2 produces the smallest average (3.33%). For $TSPLIB$ problems with a high overlap ratio, HYBRID2 and SZ2 produce the smallest average deviations (0.86% and 1.04%). GTSP2 and GTSP1 produce the largest deviations (40.78% and 103.70%). $rd400$ and $pcb442$ are challenging problems for all heuristics except for GTSP1 and GTSP2. For the $GEOMETRIC$ problems two heuristics average less than 3% (HYBRID2, HYBRID1). SZ2 and SZ1 average less than 4%.

Over all 48 problems, the four methods that find Steiner zones using Phase I of SZH (HYBRID2, HYBRID1, SZ2, SZ1) have the lowest overall average deviations, ranging from 2.48% to 3.79%.

In Table 2.4, we give the computation times (in CPU seconds) for the 15 heuristics on the 48 problems. The columns are ordered from fastest (left) to slowest (right). All heuristics except for CTD, TILE1, TILE2, YUAN+, and LK-SOCP achieve faster times as the overlap ratio increases. CTD slows down because the

trapezoidal decomposition takes more time to compute as the overlap ratio increases. The running times for TILE1 and TILE2 are linked to the overlap ratio by the stepsize parameter (the radius, r, is the stepsize) so that higher overlap ratios lead to longer computation times. The running times for YUAN+ and LK-SOCP remain relatively constant over all overlap ratios. For methods that apply Phase I, the size of the TSP solved in Phase II decreases as the overlap ratio increases. YUAN+ and LK-SOCP do not apply Phase I, so their running times do not decrease as the overlap ratio increases.

MERGE, LK-SOCP, HULL, SZ1, and SZ2 are very fast, taking one-third to one and one-half seconds on average to solve a problem. The two methods based on the generalized TSP (GTSP1, GTSP2) are computationally expensive. They take an exorbitant amount of time to solve problems (on the order of several months for the largest problems!). The hybrid methods (HYBRID1, HYBRID2), though not as slow as the GTSP methods, are much slower than the other 11 methods.

We also used the Manhattan norm on the 48 test problems and found that HYBRID2, HYBRID1, SZ2, and SZ1 were the best methods based on overall accuracy. Computation times were comparable to the Euclidean results. The complete details are given in Appendix A.

Table 2.2: Tour lengths for 15 heuristics on 48 problems with equal radius and 2D Euclidean norm

Based on the computational experiments with the 48 problems using the Euclidean norm, we observe the following. (1) As the overlap ratio increases from low to high, tour length decreases in almost all cases (except for GTSP1 on problems $rat195$, $d493$, and $dsj1000$), and computation times decrease for many heuristics, including the Steiner-zone methods (SZ1, SZ2, HYBRID1, HYBRID2), GTSP1, GTSP2, and the two methods from Dong et al. (HULL, MERGE). (2) For low and medium overlap ratios, the methods that use Steiner zones clearly outperform the methods that do not (LK-SOCP and YUAN+). This suggests that for these problems, Steiner zones improve the quality of the solution. (3) The two methods based on the generalized TSP (GTSP1, GTSP2) produce very good, short tour lengths for low and medium overlap problems if you are willing to wait months for results. These two methods produce poor tour lengths for high overlap problems with extremely long computation times. (4) The hybrid methods (HYBRID1, HYBRID2) produce results that fall between the Steiner zone methods and the GTSP methods. For low overlap problems, the hybrid methods find much better tours than the Steiner zone methods but not for the medium and high overlap problems. They are much slower than the Steiner zone methods and much faster than the GTSP methods. (5) The two methods that do not use Steiner zones (YUAN+ and LK-SOCP) perform better on most high overlap ratio problems than all Steiner-zone methods. Because LK-SOCP is so fast, it may be worthwhile to incorporate LK-SOCP into SZH as a hybrid heuristic. (6) Greedily choosing Steiner zones of the very highest degree, as in CTD, performs well, but is not as consistent as the SZH methods that build Steiner zones using an ordered list of nodes. CTD finds better tours than SZ1 and

SZ2 15 out of 48 times but has a poorer average deviation. (7) If we consider the order in which each heuristic appears in Tables 2.3 and 2.4 to be performance rankings, then SZ1 and SZ2 have the best mean ranking, 4, of all 15 heuristics tested. LK-SOCP is next with an average rank of 5. All other methods have average rank greater than 6.

2.6 Conclusions

In this chapter, we presented a new heuristic for solving the CETSP that is straightforward and easy to understand. The Steiner-zone heuristic reduces a graph of nodes to a set of Steiner zones, assigns a good tour sequence to them, and then minimizes the tour length with respect to the Steiner zones. We compared 15 different heuristics for solving the CETSP on 48 test problems. We found that the combination of low computation time and high solution quality made the Steiner-zone heuristics very competitive methods.

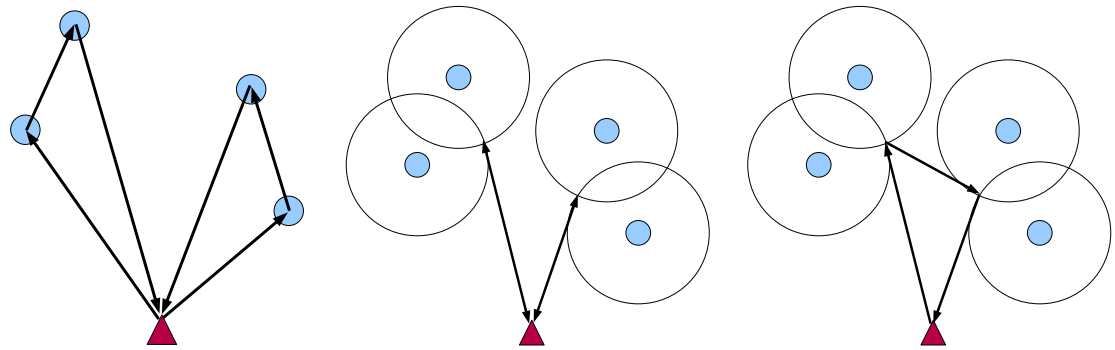
Chapter 3

The Close-Enough Vehicle Routing Problem

3.1 Introduction

In the Vehicle Routing Problem (VRP), k vehicles start at a single depot and visit n nodes such that each node is serviced by exactly one vehicle. Given a complete, undirected graph $G = (V, E)$, where V is the set of n nodes, E is the set of edges, and each edge has a symmetric distance, we must find the set of tours (Hamiltonian cycles) that minimizes the sum of the edge lengths. Each node has a demand that must be serviced in its entirety by a single vehicle. Each vehicle has a maximum tour length and a capacity restriction.

In this chapter, we model and solve a new variant of the VRP. If a vehicle is within a specified distance of a node, then the node is considered to have been serviced. We illustrate the CEVRP in Figure 3.1. In the standard VRP shown in Figure 4.1(a), two vehicles leave the depot, visit two nodes each, and return to the depot. In the CEVRP shown in Figure 4.1(b), the vehicles need to get within distance r of each node (this is depicted by the disks around each node). If each vehicle visits the intersection of two disks, all four nodes have been visited and the two routes are a feasible solution to this CEVRP. If maximum route length and capacity restrictions are not violated, then one vehicle can visit all four nodes as shown in Figure 3.1(c). The solutions in Figures 4.1(b) and 3.1(c) are clearly shorter



(a) VRP solution; the depot is depicted by a triangle.

(b) CEVRP solution with two vehicles

(c) A possible CEVRP solution that uses one vehicle and does not violate distance and capacity limits.

Figure 3.1: The optimal VRP solution compared to optimal CEVRP solutions. Both CEVRP solutions are shorter.

than the solution in Figure 4.1(a).

In the remainder of this chapter, we describe a single-depot, homogeneous fleet, capacitated CEVRP with route-length restrictions. There is no limit on the number of vehicles available, and nodes do not have service times.

The CEVRP can be applied to unmanned aerial vehicle (UAV) reconnaissance. To collect information on a set of intelligence targets, a user may deploy a fleet of UAVs. The aircraft need only get within a specified distance, r, of each target's center to collect the intelligence. Each aircraft has an upper bound on its flying time and has finite data storage capacity so that routes must be constructed that get close enough to all targets while minimizing distance traveled.

The chapter is organized as follows. In Section 5.2, we review the literature on the CETSP and VRP. In Section B.1, we formulate the CEVRP as a mathematical program. In Section 5.5, we develop a heuristic solution procedure based on intersections of disks called Steiner zones. In Section 3.5, we generate a set of test

problems and conduct extensive computational experiments in which we compare results produced by our heuristic to the results of several solution methods. We give our conclusions in Section 5.7.

3.2 Literature Review

The first description of the CETSP is given by Gulczynski, Heath, and Price [43]. They consider utility companies that use Radio Frequency Identification (RFID) to read meters from a distance. The authors present six heuristics for solving problems with Euclidean distances. The six heuristics have three steps in common.

- Step 1. Find a feasible supernode set S such that all customers are within r units of at least one point in S.
- Step 2. Solve a TSP on the points in S to produce a near-optimal solution T that is a feasible solution to the CETSP.
- Step 3. Reduce the distance traveled in T while maintaining feasibility.

Dong, Yang, and Chen [27] formulate the CETSP as a mixed integer, nonlinear program, but they do not attempt to solve it. Instead, they develop two heuristics that use clustering or convex hulls to generate the supernodes. Yuan, Orlowska, and Sadiq [73] consider the problem of routing a mobile robot to visit sensors that are distributed in the Euclidean plane. In order to communicate with a sensor and download data, a robot must be within a specified distance of the sensor (the effective range is specified by a disk of radius r and disks do not overlap). The

authors develop an evolutionary approach for solving the robot routing problem. The approach was effective but very slow. Shuttleworth et al. [65] extend the CETSP to street networks. They consider a real-world meter reading problem that uses actual data from a utility company. The authors solve the problem using a two-stage process. Their solutions save time and distance when compared to the existing route used by the utility company.

In Chapter 2, we described a Steiner-zone heuristic (SZH) for solving the CETSP in two dimensions using Euclidean and Manhattan norms, where r is the same for all nodes. We reduced a graph of nodes into a graph of disk intersections (the intersection of k disks is called a Steiner zone of degree k), solved a TSP on points from each region, and then minimized the distance of this tour. We generated a set of test problems and compared the results of the Steiner-zone heuristic to the results produced by 13 heuristics including two genetic algorithms, two hybrid methods combining Steiner zones and a genetic algorithm, and two simple methods. For problems where there was only small or medium overlap of disks, the genetic algorithms consistently found the shortest tours but were very slow. The Steiner-zone methods were extremely fast over all problems and produced the best solutions for problems where there was a large amount of disk overlap.

The book by Vigo and Toth [68] contains papers that discuss the standard VRP and its variants and describe successful solution approaches. The latest work on the VRP is given in the book by Golden, Wasil, and Raghavan [38] and the bibliography from Cordeau et al. [21]. Groër [39] combines integer programming, the record-to-record travel metaheuristic, and parallel computing to produce very

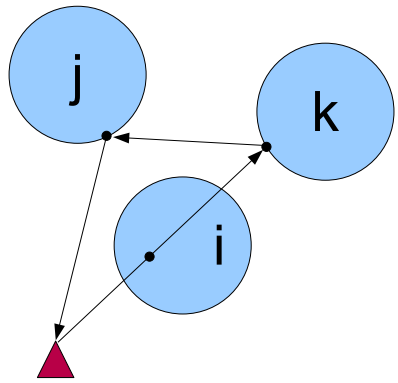


Figure 3.2: Three representative points are shown as small black circles, one for each disk.

high quality solutions to standard VRP test problems.

3.3 Formulation

In this section, we formulate the CEVRP as a mixed-integer nonlinear program. In the CEVRP, at least one route must cross a disk of radius r surrounding every node i as shown in Figure 3.2. The radius is the same for every node. We denote the disk surrounding node i as $disk(i)$. Any route that touches or passes through $disk(i)$ visits node i (with the exception of the depot (node 0) which has no disk). Node i is a fixed point in the plane at coordinate (a_i, b_i). We denote this as $orig(i)$, the origin of node i. We assume that $orig(i) \neq orig(j)$ for all i and $j \geq 0$. The depot, however, may have the same coordinates as node i. There is no service time requirement at any node. Let ϵ be the smallest non-zero length of any edge. Requiring all edges to have non-zero length does not eliminate feasible solutions when the depot has the same coordinates as node i as long as ϵ is sufficiently close to zero.

Let (x_i, y_i) be the coordinate on a vehicle's tour that is close enough to node i. Coordinate (x_i, y_i) is known as node i's *representative point*. x_i and y_i are unbounded continuous variables. In Figure 3.2, we illustrate the concept of representative points. Any of the points on the line through $disk(i)$ can be selected as node i's representative point. Distances in the CEVRP are given by $\sqrt{(x_i - x_j)^2 + (y_i - y_j)^2}$. Let e_{ijk} be a binary variable equal to 1 if node i immediately precedes node j on vehicle k's tour and 0 otherwise. w_{ik} is a binary variable equal to 1 if node i is visited by vehicle k. t_i is the continuous variable representing the arrival time at node i. K is the number of vehicles available. Q and T are constants representing the maximum capacity and tour length for all K vehicles, respectively. Our mixed-integer formulation of the CEVRP is given below.

$$\text{Minimize} \quad \sum_{i=0}^{n} \sum_{j=0}^{n} \sum_{k=1}^{K} e_{ijk} \sqrt{(x_i - x_j)^2 + (y_i - y_j)^2} \tag{3.1}$$

subject to

$$x_0 = a_0; \; y_0 = b_0 \tag{3.2}$$

$$(x_i - a_i)^2 + (y_i - b_i)^2 \leq r^2 \qquad i = 1, \ldots, n \tag{3.3}$$

$$\sqrt{(x_i - x_j)^2 + (y_i - y_j)^2} \geq \epsilon \qquad \forall\, i, j \tag{3.4}$$

$$w_{0k} = 1 \qquad \forall\, k \tag{3.5}$$

$$t_0 = 0 \tag{3.6}$$

$$\sum_{k=1}^{K} w_{ik} = 1 \qquad i = 1, \ldots, n \tag{3.7}$$

$$\sum_{i=1}^{n} q_i w_{ik} \leq Q \qquad \forall\, k \tag{3.8}$$

$$\sum_{i=0}^{n} e_{ijk} = \sum_{i=0}^{n} e_{jik} = w_{jk} \qquad \forall\ j, k \tag{3.9}$$

$$t_i + e_{ijk} d_{ij} - (1 - e_{ijk})T \leq t_j \qquad \forall\ k;\ i \geq 0,\ j \geq 1 \tag{3.10}$$

$$t_i + e_{ijk} d_{ij} + (1 - e_{ijk})T \geq t_j \qquad \forall\ k;\ i \geq 0,\ j \geq 1 \tag{3.11}$$

$$0 \leq t_i + d_{i0} \leq T \qquad \forall\ i \geq 1 \tag{3.12}$$

$$\sum_{i,j \in S} e_{ijk} \leq |S| - 1 \qquad \text{for } S \subseteq \{1, \ldots, n\},$$

$$2 \leq |S| \leq n\ \forall\ k \tag{3.13}$$

$$e_{ijk} \in \{0, 1\},\ (x_i, y_i) \in R \times R \qquad \forall\ i, j, k \tag{3.14}$$

The objective function (3.1) minimizes the total distance of all tours. However, the distance coefficients are not constants. The coefficients are functions of the representative points. In Figure 3.3, we show how different choices of representative points affect the edge distance between node i and node j. Constraints (3.2) to (3.4) are the close-enough constraints while (3.5) to (3.13) are the VRP constraints.

Constraint (3.2) forces the representative point for the depot to lie at its origin, (a_0, b_0). Constraint (3.3) requires each representative point i to lie within a disk around $(a_i,\ b_i)$. The index does not include the depot ($i = 0$) as there is no disk around the depot. Constraint (3.4) requires the distance between any two representative points to be strictly positive. Without (3.4), edges in the tour can have length 0. If k disks have the same representative point, all $\binom{k}{2}$ edges between the k disks have length 0 and could be selected without increasing the objective function value. Assignment constraints (3.9) ensure that exactly one edge enters and one edge exits each node. However, without (3.4), a node can have multiple predecessors and

successors. In preliminary experiments, a solver was unable to find a feasible solution for very small problems where zero-length edges are possible. When constraint (3.4) is included, zero-length edges cannot occur and the assignment constraints ensure a single predecessor and successor for each node. Consider the problem in Figure 3.1(c) where there are only two unique points representing four disks. If this problem is solved using the formulation including constraint (3.4), each representative point is replaced by two points ϵ units apart. For values of ϵ sufficiently close to zero, our formulation produces the same optimal routes as if we could solve with $\epsilon = 0$.

Constraint (3.5) requires all vehicles to visit the depot and (3.6) sets the arrival time at the depot as 0. Without these two constraints, arrival times will not be computed correctly. Constraint (3.7) requires all nodes to be visited while (3.8) enforces the capacity constraints on each vehicle. In (3.9), each node is required to have exactly one predecessor and one successor. Together, (3.5) and (3.9) force the solution to use all K vehicles. Constraints (3.10) and (3.11) require the arrival time at node j to equal the arrival time at node i plus the distance between the two if and only if i immediately precedes j in route k. They may be rewritten as:

$$t_i + e_{ijk}(d_{ij} + T) - t_j \leq T \qquad \forall\ k;\ i \geq 0,\ j \geq 1 \tag{3.15}$$

$$t_i + e_{ijk}(d_{ij} - T) - t_j \geq -T \qquad \forall\ k;\ i \geq 0,\ j \geq 1 \tag{3.16}$$

Constraint (3.12) forces each route to return to the depot within the prescribed distance limit. Finally, constraint (3.13) prohibits subtours by forcing the number of edges in any subset of non-depot nodes to be at most one less than the subset's cardinality. Although (3.10) makes (3.13) redundant, we include it based on the

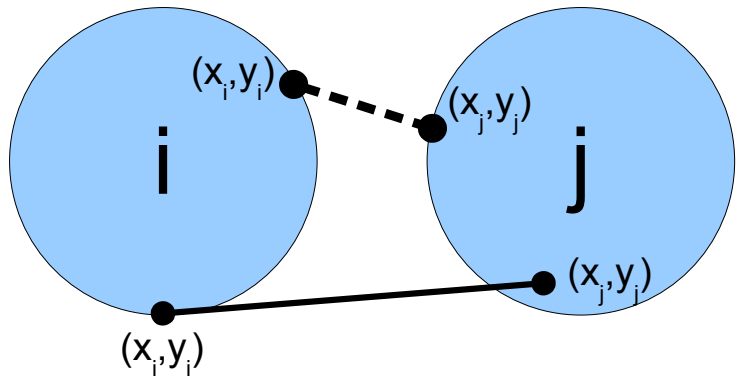

Figure 3.3: The two lines connect representative points for nodes i and j.

computational experience in [40]; including (3.13) should reduce computation time.

The CEVRP reduces to the VRP when $r = 0$ for all i. If $K = 1$, then the CEVRP reduces to the CETSP. When $r = 0$ for all i and $K = 1$, the CEVRP reduces to the TSP.

3.4 Heuristic

3.4.1 Definitions

Let $SZ(k)$ denote a Steiner zone of degree k. $SZ(k)$ is the non-empty intersection of k convex regions. In this case, the regions are disks. Any point in $SZ(k)$ is close enough to all k member nodes, as shown in Figure 4.2. A Steiner zone of degree 1, $SZ(1)$, is called a *singleton*. In Figure 3.5, we show two Steiner zones of equal degree that differ in the amount of overlap or intersection. A point in a Steiner zone is in general not one of the original nodes to be visited, but a visit to this point may reduce the total length of the tour. These zones affect the TSP the same way Steiner points affect the minimal spanning tree problem. The name

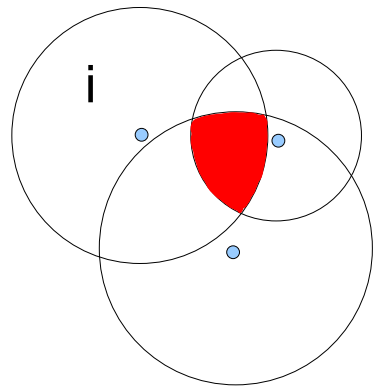

Figure 3.4: The shaded region is a Steiner zone of degree 3 with base node i and is denoted $SZ(3)$. $SZ(3)$ is the intersection of three disks.

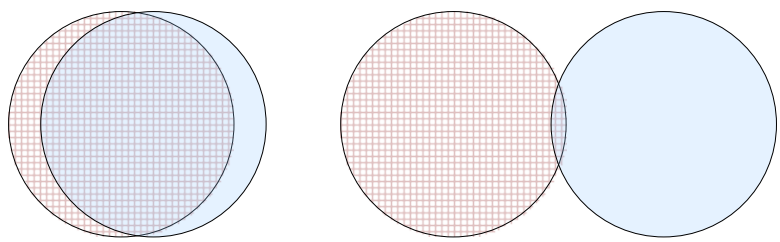

(a) large intersection (b) small intersection

Figure 3.5: The Steiner zones have degree 2 in both cases.

Steiner zone comes from this observation.

Given $orig(i)$, $SZ(k)$ with base node i is characterized by the polar angles, relative to $orig(i)$, with which the $k-1$ other disks intersect node $disk(i)$. These angles are easily obtained for two disks knowing only the origins and radii of the two disks. We provide an example in Figure 4.8. To specify $SZ(k)$, we need only $orig(i)$ and the upper and lower angles of intersection. Note that the perimeter of each disk crosses $disk(i)$ at most twice. We refer to these as intersection points.

In Figure 3.1, the potential savings in tour length increases with r. In Figure 4.1(a), $r = 0$ (although we show disks around the nodes for illustration) and the optimal CEVRP result is the optimal VRP solution. If $r > 0$, as in Figures 4.1(b)

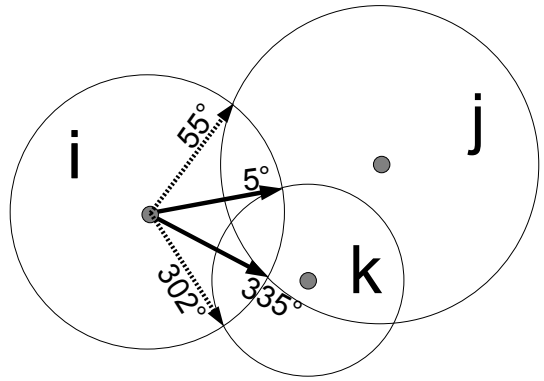

Figure 3.6: Node i is the base node. Only the lower (343°) and upper (8°) angles of intersection are required to specify the $SZ(3)$ formed by $disk(i)$, $disk(j)$, and $disk(k)$.

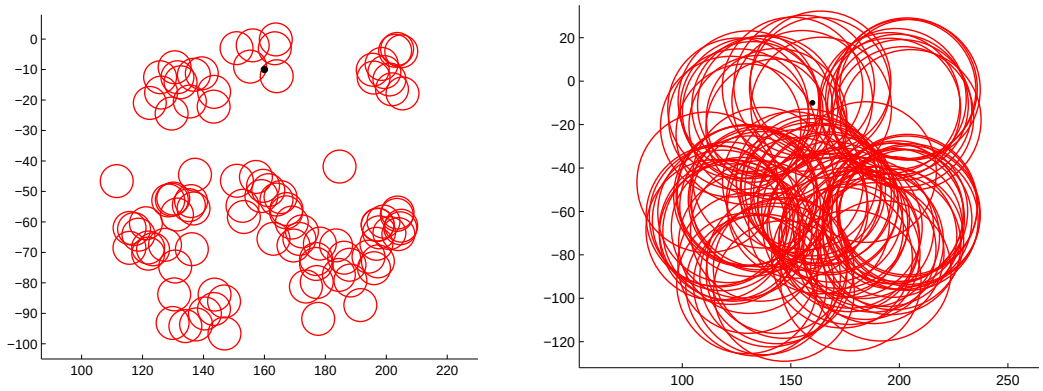
and 3.1(c), we expect the optimal CEVRP solution to be shorter than the optimal VRP solution. When r is large enough so that every node i is within r of the depot, then the optimal solution would have a total distance of zero.

We define a single metric, *overlap ratio*, to indicate how much potential there is for improvement of the CEVRP solution over the VRP solution. For a given CEVRP, let $l_{contain}$ be the length of a side of the smallest square containing all n disks. The *overlap ratio* is the ratio of r to $l_{contain}$. In Figure 3.7, we show two different overlap ratios for the same set of nodes. We consider instances with an overlap ratio much larger than 0.3 uninteresting because almost any sequence of n nodes will produce a near-optimal solution to the CEVRP. Overlap ratio is not appropriate for problems which lie in an elongated rectangle rather than a square, but it provides an indication of how much improvement is possible.

SZH reduces a graph of n nodes to a graph of m Steiner zones, finds a set of feasible tours through these zones, and locates the best representative point for



(a) overlap ratio 0.05 (b) overlap ratio 0.2

Figure 3.7: The nodes are the same in (a) and (b), but the radius is larger in (b). The larger the overlap ratio, the greater the potential savings.

each node in order to minimize the total distance of the routes. We now describe the three phases of our heuristic.

3.4.2 Phase I - Graph Reduction

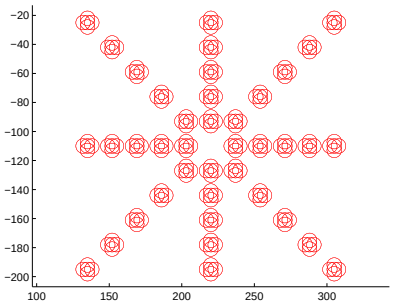
We sort all n nodes and place them in a list, denoted $list$. The first node is removed from the list, say node i, and we compute most of the Steiner zones that can be formed with i. Computing all possible Steiner zones would be computationally expensive. In addition, using only the Steiner zones of the very largest degree generally does not produce the best tours as shown in Chapter 2. The list of Steiner zones formed with i, denoted SZ_list_i, is stored from highest degree to lowest. Steiner zones of equal degree are stored lexicographically. For example, the four Steiner zones {1,2}, {1,6,4}, {1,2,3,4,5}, and {1,2,5} would be stored as {1,2,3,4,5}, {1,2,5}, {1,6,4}, and {1,2}.

We compute most of the Steiner zones associated with node i as follows. Given the current SZ_list_i and the next node to be considered from $list$, say node j,

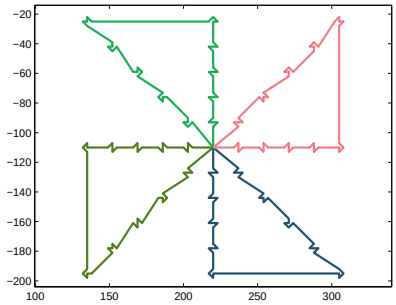
compute the angles of intersection for Steiner zone $\{i, j\}$, if it exists. If Steiner zone $\{i, j\}$ exists, we start at the beginning of SZ_list_i and move to the end, comparing each Steiner zone's angles of intersection to those of $\{i, j\}$. At the first (and therefore highest degree) Steiner zone in SZ_list_i whose angles of intersection have a non-empty overlap with those of Steiner zone $\{i, j\}$, we create the new Steiner zone along with new Steiner zones based on node i of degree two or three that we have found.

Consider $SZ_list_1 = \{1, 2, 3, 4, 5\}, \{1, 2, 5\}, \{1, 6, 4\}$, and $\{1, 2\}$, and let j be node 8. Let 1 and 8 have a non-empty intersection at angles 10° and 30°, that is, they form a $SZ(2)$. First, we compare those angles to the angles for Steiner zone {1,2,3,4,5}, then with {1,2,5}, and so on until we find a non-empty intersection. If none is found, add {1,8} to the end of SZ_list_1. Suppose that the angles of intersection for {1,2,3,4,5} are 0° and 12°. Since [0,12] and [10,30] overlap, a new Steiner zone of degree 6 has been found and Steiner zone {1,2,3,4,5,8} is added to the beginning of SZ_list_1. Node 8 must share an intersection with all smaller combinations of nodes 1, 2, 3, 4, and 5. Therefore, as described in Chapter 2, we add to SZ_list_1 any Steiner zones based on node 1 of degree two or three that had not already been added. This makes Phase I fast and effective. In practice, we find Steiner zones of degree 100 or more in a fraction of a CPU second.

After we have processed all the nodes remaining in *list*, we remove the Steiner zone of highest degree from SZ_list_1 and remove all its component nodes from *list*. The next remaining node in *list* is then chosen, and the process is repeated until $list = \emptyset$. Since each node in a VRP has a demand that must be satisfied in its



(a) 200-node CEVRP



(b) A near-optimal standard VRP solution with a total length of about 1535.

Figure 3.8: 200-node CEVRP and a near-optimal VRP solution.

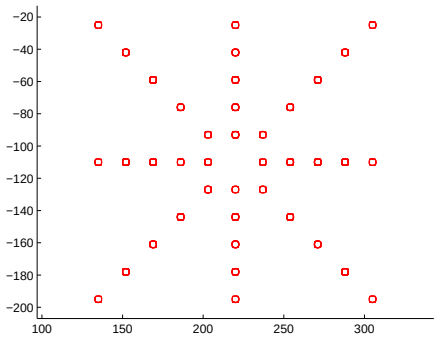


Figure 3.9: 200-node CEVRP after Phase I. There are 40 Steiner zones.

entirety by a single vehicle, care must be taken in Phase I to create Steiner zones whose cumulative demand is no larger than the maximum vehicle capacity.

In Figure 3.8, we show a 200-node CEVRP based on a problem from Chao et al. [15]. The test problems in Chao et al. [15] have visually estimated solutions that are high quality. To visually estimate a CEVRP solution, we replaced every node from the VRP problem with five intersecting nodes and used node demands given in Chao et al. [15]. For example, the node demand in the eight sets of five nodes closest to the depot is 12 units. The demand decreases the further away

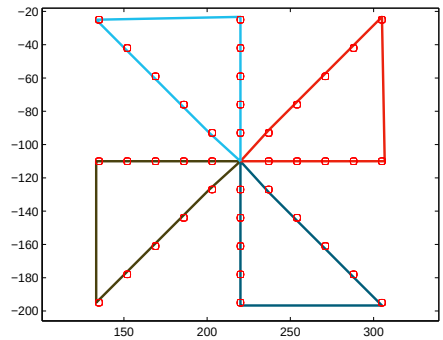

Figure 3.10: 200-node CEVRP after Phase II. The total length is about 1176.

from the depot each set of five nodes is, decreasing from 12, to 8, 4, 2, and finally 1. In Figure 3.8(b), we show a near-optimal solution to the VRP with a capacity of 270 per vehicle. In Figure 3.9, we show that applying Phase I to this problem has reduced the 200 nodes to 40 Steiner zones of degree 5. The Steiner zones are disjoint. The Phase I algorithm does not explicitly require or encourage disjoint Steiner zones.

3.4.3 Phase II - Routing

The result of applying Phase I to graph G is graph G'. G' is a graph of m Steiner zones rather than the original n nodes. In order to find a set of routes, we designate a single point in each Steiner zone as its representative point and apply a VRP solver to these points. The result is a feasible solution to the CEVRP.

3.4.4 Phase III - Tour Improvement

The result of applying Phase II to G' is a feasible solution to the CEVRP. The sequence in which each tour visits its Steiner zones is fixed, but the location of each Steiner zone's representative point can still be modified. In Figure 3.10, we show the results after applying Phase II to the 200-node CEVRP. We notice that the tour length is much less than the tour length of the near-optimal VRP solution. The tour could be further shortened by changing the representative points for the Steiner zones. To determine the optimal placement of the representative points, we solve the Touring Polygons Problem (TPP)[29] for each route in the Phase II solution where we consider convex regions (Steiner zones) instead of polygons. We call this the Touring Steiner Zones Problem (TSZP). Given a tour on a set of disks, the TSZP minimizes the distance such that each Steiner zone (and thus each disk) remains feasibly covered, and the sequence of Steiner zones visited remains unchanged.

In Chapter 2 we presented two solution procedures for the TSZP. The first, called $SOCP$, is an exact procedure using a Second Order Cone Program (SOCP) formulation and is solved using CPLEX [2]. It solves problems optimally in two and three dimensions for Euclidean and Manhattan norms and does not require the Steiner zones to be disjoint. Problems with 1001 nodes are solved in less than six CPU seconds. When the radii for the disks are different, numerical issues with CPLEX require solving the TSZP as a general nonlinear program.

The second procedure is a heuristic, called IP_{PhIII}, that solves an integer program at each iteration. In Chapter 2 we found that the heuristic frequently con-

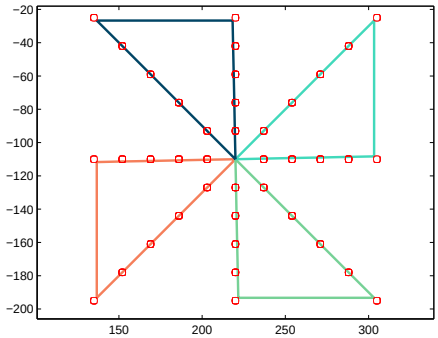

Figure 3.11: 200-node CEVRP after Phase III. The total length is about 1131.

verged to the optimal TSZP solution and was never more than 1% from optimality. At each iteration, a Steiner zone is approximated by three points. After 10 iterations, each Steiner zone has been approximated by a 1536-sided polygon, and the TPP has been solved to near optimality. IP_{PhIII} solves problems with 1001 nodes in less than one CPU second. It has none of the numerical issues associated with $SOCP$, but can only be used in 2D problems where the Steiner zones are mostly disjoint.

In Figure 3.11, we show the final result for a 200-node $CEVRP$ after applying Phase III. The total distance has been reduced considerably. This appears to be a very good solution.

3.5 Computational Experiments

3.5.1 VRP Solver

Recently, Groër [39] developed a record-to-record (RTR) travel procedure to solve several of the VRP variants, including the standard single-depot capacitated

vehicle routing problem (CVRP). He also developed a parallel algorithm combining RTR with integer programming that found nearly all the best-known solutions and generated new best-known solutions to the CVRP. The serial version of his code produced solutions that were competitive with those of the best codes currently available.

Record-to-record travel works in uphill and downhill phases. During the uphill phase, any move that is no worse than some percentage (deviation) from the current best solution (record) is accepted. During the downhill phase, only strictly improving moves are accepted. The uphill phase is run for a fixed number of iterations while the downhill phase ends only when no improving move has been found. After a series of uphill and downhill moves are finished, the solution may be perturbed and the entire process repeated.

The RTR algorithm in [39] starts with a solution produced by a modified Clarke-Wright savings procedure. Groër uses local optimization procedures including one-, two-, and three-point-movement, two-, three-, and or-opt, and a procedure called cross-exchange. These are all explained, with examples, in [39]. The k nearest neighbors for each node are stored.

We use Groër's code to solve Phase II. Our default settings run RTR three different times, using the modified Clarke-Wright procedure with $\lambda = 0.6$, 1, and 1.2. The size of the neighbor list is 25. Each uphill phase is run for 30 iterations. The uphill and downhill cycle phases are run five times after which we stop (the solution is not perturbed). We used the serial version of his code.

3.5.2 CEVRP Heuristics

We coded eight different CEVRP solution methods. SZVRP1 is the Steiner-zone heuristic where we solve Phase II using the modified Clarke-Wright savings procedure with $\lambda = 1$ and do not use the RTR heuristic. To solve Phase III, we apply IP_{PhIII} until each Steiner zone is approximated by a 1536-sided polygon. Each individual route is then post-processed using the chained Lin-Kernighan TSP heuristic implemented in the Concorde software package [1]. This method emphasizes computational speed over tour length.

SZVRP2 is the same as SZVRP1 except that we solve Phase II using Groër's RTR code with one-point and two-point-movement and two-opt, a neighbor list of size 10, and no perturbations. We initialize the RTR heuristic using the modified Clarke-Wright savings procedure with $\lambda = 1$. This method balances computation speed and tour length.

SZVRP3 is the Steiner-zone heuristic with the SOCP optimal Phase III solver in which the Phase II - Phase III cycle is repeated until no improvement is found. Phase II is solved using the RTR code with our default settings. This method emphasizes tour length over computational speed.

SZVRP4 is the same as SZVRP3 except that we use all local optimization routines specified by Groër except for cross-exchange. We use a neighbor list of size 75 and perform one perturbation. This method emphasizes tour length over computational speed.

GTSP-VRP finds near-optimal solutions to a generalized TSP (GTSP) ap-

proximation of the CETSP using a genetic algorithm developed by Silberholz and Golden [67]. By replacing each disk with k points, we create a GTSP where there are n clusters to be visited, each with k possible points from which to choose. Given the CETSP tour sequence found by solving the GTSP, we construct a set of Steiner zones. We solve Phase II using Groër's RTR solver with our default settings and apply the Phase III SOCP tour improvement algorithm to each route in the solution. We repeat the Phase II - Phase III cycle until no improvement is found. We used 24-point approximations of each disk. Our GTSP problem sizes range from 2,400 nodes to 24,000 nodes plus the depot.

CTD, circular trapezoidal decomposition, is a modification of Mulmuley's randomized trapezoidal decomposition algorithm [55]. It finds the highest degree Steiner zones possible in a graph. CTD subdivides a graph of disks into non-overlapping regions such that each region is bordered on the left and right by imaginary vertical lines and on the top and bottom by arcs of a disk. Using this subdivision, we compute the degree of all distinct regions in the graph and greedily select the regions with the highest degree. We break apart those zones whose total demand is larger than the maximum route capacity. Each region is assigned a feasible representative point. We solve Phase II using Groër's RTR code with default settings and then apply the Phase III SOCP formulation to each route. See Appendix F for more details.

CW-SOCP does not use Steiner zones. It uses only Phases II and III of our heuristic. It finds a high-quality feasible set of routes for the original nodes using the Clarke-Wright heuristic (Phase II) and applies the Chained Lin-Kernighan heuristic

to each route. CW-SOCP solves the Phase III SOCP for each route to optimality. The Phase II - Phase III cycle is run exactly once, and each individual route is not post-processed after Phase III using a TSP heuristic. Clarke-Wright is run only once with $\lambda = 1$.

TSP-VRP uses the route-first-cluster-second approach known as the Giant TSP. Phase I is applied and Concorde's Chained Lin-Kernighan code [1] is run on the representative points for all Steiner zones to obtain a near-optimal TSP tour. We start at the beginning of this tour and move to the end, filling one vehicle at a time. When adding the next Steiner zone exceeds the vehicle's capacity, we try to divide the Steiner zone into two zones to use as much of the vehicle's capacity as possible. To best divide the Steiner zone, we apply the first-fit-decreasing and first-fit-increasing bin-packing heuristics. Once splitting the TSP into VRP routes is finished, we apply the Phase III SOCP formulation to each route.

To the best of our knowledge, there are no published results against which to compare the Steiner-zone method. The CEVRP is a nonconvex mixed integer nonlinear program (MINLP), and as such, must be reformulated as a convex MINLP to produce valid lower bounds. In Chapter 2 we derived valid lower bounds for the CETSP that were too weak to be of any use. Any CEVRP bounds derived from the CETSP lower bounds will be too weak to provide any indication of how close to optimality our solutions are. Therefore, until tight bounds are derived and/or other heuristics published, we cannot definitively prove exactly how good or bad each heuristic is.

3.5.3 Problem Instances

We constructed CEVRP test problems by adding node demands and constraints on vehicle capacity and maximum tour distance to all 48 CETSP instances generated and described in Chapter 2. All problem data are given in Appendix L.

3.5.4 Computational Results

All experiments were performed on a 2.4 GHz Pentium machine with 3 GB RAM running Windows XP Professional. Solutions are checked for within-disk, distance, and capacity feasibility.

The results produced by eight methods (SZVRP1, SZVRP2, SZVRP3, SZVRP4, GTSP-VRP, CTD, CW-SOCP, TSP-VRP) on the 48 problems are given in Table 3.1. We report results to two decimal places. The bold font indicates the best value. In Table 3.2, we computed the percentage deviation from the best solution for the results given in Table 3.1. The columns in both tables are ordered from best (left) to worst (right) by overall average deviation.

In Table 3.1, for the low overlap ratio $TSPLIB$ problems, SZVRP4 produces three best solutions and SZVRP3 two best solutions. For the medium and high overlap ratios, CW-SOCP produces five best solutions. For the $GEOMETRIC$ problems, SZVRP3 finds 13 best solutions, and both SZVRP4 and CW-SOCP find six.

For the low overlap ratio $TSPLIB$ problems, three methods (SZVRP3, SZVRP4, CTD) have average percentage deviations that are less than 1%. SZVRP4 produces

the smallest average (0.20%). For the medium overlap ratio, CW-SOCP has the smallest average (2.06%) with the remaining seven methods having an average of 4% to 5%. For the high overlap ratio, CW-SOCP has the smallest average (1.42%) with the four Steiner zone methods averaging 5.89%.

Over all 21 $TSPLIB$ problems, SZVRP4 produces the smallest average (3.40%), closely followed by SZVRP3 (3.54%) and SZVRP2 and CW-SOCP (both at 3.82%). Three Steiner-zone methods perform well using all three overlap ratios. CW-SOCP does not perform well on problems with a low overlap ratio but is clearly the best method for problems with medium and high overlap ratios.

Looking at the $GEOMETRIC$ problems, we see that CW-SOCP produces the smallest average deviation for the seven $Team$ problems (2.97%) while the remaining methods averages under 6.00%. CTD and GTSP-VRP average less then 2.00% deviation (1.51%, 1.73%) for the $ConcentricCircles$ problems. SZVRP3 and SZVRP4 produce the smallest averages for the $Bubbles$ problems (0.54%, 1.50%). CW-SOCP performs very poorly on both sets of problems (13.73%, 30.37%). For the $RotatingDiamonds$ problems, six heuristics have an average of less than 3.00%. Over all $GEOMETRIC$ problems, SZVRP3 produces the smallest average (2.62%). Four methods (SZVRP2, SZVRP4, CTD, GTSP-VRP) produce an average less than 4.00%.

Over all 48 problems with 2D, Euclidean norm, three Steiner zone methods (SZVRP2, SZVRP3, SZVRP4) have the best average deviations, all under 4.00%. Five methods have an average deviation that is two to three times greater.

In Table 3.3, we give the computation times for the eight methods. As the

overlap ratio increases for the $TSPLIB$ problems, we see that the computation time decreases. Over all 21 problems, CW-SOCP is very fast with an average time of less than one second. Three methods (SZVRP1, SZVRP2, TSP-VRP) average less than six seconds. For the 27 $GEOMETRIC$ problems, CW-SOCP and SZVRP1 have an average less than one and one half CPU seconds and SZVRP2 averages less than four CPU seconds. Over all 48 problems, CW-SOCP is the fastest (1.140 seconds) with SZVRP1 close behind (1.982 seconds). SZVRP2 and TSP-VRP average less than seven seconds. CTD, SZVRP3, and SZVRP4 are moderately slow, averaging between 16 and 46 seconds, and GTSP-VRP is extraordinarily slow.

For the $TSPLIB$ problems that were solved using the Euclidean norm, we observe that the choice of Steiner zones matters for the low overlap ratio. The four Steiner-zone methods and CTD all place a large amount of effort into determining Steiner zones and are clearly better than CW-SOCP, which does not use Steiner zones. For the medium and high overlap ratios, the choice of Steiner zones does not appear to affect solution quality. For these problems, CW-SOCP clearly is the best.

Over all 48 test problems, we observe the following: (1) SZVRP2 has the best balance between speed and solution quality of the four Steiner zone methods; it produces some of the smallest average deviations overall and is fast; (2) spending too much time solving Phase II leads to diminishing returns for the Steiner zone methods as SZVRP4 demonstrates; SZVRP4 generally is as accurate as SZVRP3 but at a much higher computational cost; spending too little time, as with SZVRP1, almost never finds the best solutions; (3) CW-SOCP, conceptually the simplest algorithm, performs well on problems with medium and high overlap ratios but performs poorly on the problems with low overlap ratios (interestingly, the modified Clarke-Wright VRP solver produced only one best solution when applied to Steiner zones as in SZVRP1); CW-SOCP is the fastest algorithm; and (4) If we consider the order in which each heuristic appears in Tables 3.2 and 3.3 to be performance rankings, then SZVRP2 has the the best mean ranking, 3, of all eight heuristics tested. SZVRP1 and SZVRP3 are next with an average rank 3.5 while SZVRP4, CW-SOCP, and CTD all follow with an average rank of 4.5.

Our results indicate that underlying problem structure affects the performance of CW-SOCP. For most low overlap ratio problems, it performs poorly. For most medium and high overlap ratio problems, it performs well. Those results, along with the dominance of the methods explicitly using Steiner zones (SZVRP1, SZVRP2, SZVRP3, SZVRP4 and CTD) on low overlap ratio problems provide strong evidence that the choice of Steiner zones has a positive impact on the performance of SZH.

We also used the Manhattan norm on the 48 test problems and found similar results: SZVRP2, SZVRP3, and SZVRP4 were the best methods based on overall

accuracy. CW-SOCP and SZVRP1 were the fastest methods. SZVRP1 and SZVRP2 had the highest average performance ranking (3.5) based on average deviation and computation times. The complete details are given in Appendix A.

3.6 Conclusions

In this chapter, we presented a new routing problem, the CEVRP, and formulated it as a mathematical program. We described a heuristic for solving the CEVRP, SZH, that is straightforward and easy to understand. SZH reduces a set of nodes to a set of Steiner zones, assigns a set of routes to them, and then minimizes the sum of the route lengths with respect to the Steiner zones. We compared four versions of SZH against four different methods on 48 test problems. Over all problems, we found that SZH, combined with a fast but high-quality VRP solver, produced consistently good results in a short amount of time. The combination of computational speed and solution quality makes SZVRP1 and SZVRP2 highly competitive methods.

In future work, we will apply the Steiner-zone heuristic to problems where the radius for each disk is different and extend it to solve problems in three dimensions. We will develop a post-processor for the Steiner-zone heuristic in order to improve our results with relatively little increase in computational cost.

Chapter 4

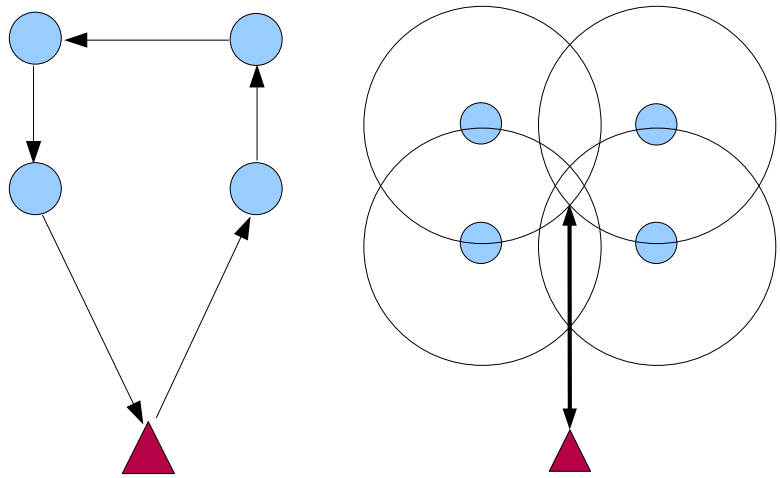
Improving the Steiner-zone Heuristic

4.1 Introduction

Until recently, algorithm design has been constrained by low computational power. In the past, simple heuristics were created that produced good solutions very quickly using limited resources. These methods were fast because they had relatively small search neighborhoods. The local minima in these neighborhoods generally are not globally optimal solutions (they can be over 20% away from optimality [47]). Examples include greedy Traveling Salesman Problem (TSP) heuristics such as the nearest-neighbor and nearest-insertion heuristics and local improvement methods for the TSP such as two-opt improvement [22, 60].

Processing power has increased dramatically, and more effective algorithms, called metaheuristics, have appeared. Metaheuristics use different mechanisms to escape local minima, allowing a much more thorough exploration of the entire search space. Examples include record-to-record travel, evolutionary computation, simulated annealing, and ant-colony optimization [28, 46, 48].

Metaheuristics are often designed with computational speed as only a secondary consideration to accuracy. In this chapter, we improve the Steiner-zone heuristic (SZH) in a way that combines the best aspect of simple, greedy heuristics such as SZH (speed) with the best aspect of metaheuristics (accuracy). We



(a) TSP tour (b) CETSP tour

Figure 4.1: The optimal TSP tour compared with the optimal CETSP tour. The CETSP tour is shorter.

develop a new variant of SZH called the minimum-angle heuristic (MAH) and a post-processing step for SZH called Phase IV. We test our modifications on the same CETSP and CEVRP problems given in Chapters 2 and 3 and compare the new solutions to best-known solutions.

In the CETSP, a salesman starts and ends at the same city and must find the cheapest way to visit all n cities exactly once. Each city is visited if the tour comes within r units of the ith city, for all i. Given a complete, nondirected (for the symmetric version) graph $G = (V, E)$, where V is the set of n nodes (cities) and E is the set of edges, we must find the tour (Hamiltonian cycle) that minimizes the sum of the lengths of the edges. The length of each edge e_{ij} is a function of the points at which the salesman visits nodes i and j. The CEVRP is a multi-vehicle extension of the CETSP. Each node must be visited by exactly one of K vehicles. A demand is associated with each node. Each vehicle has a maximum capacity and maximum tour length. All nodes must be visited.

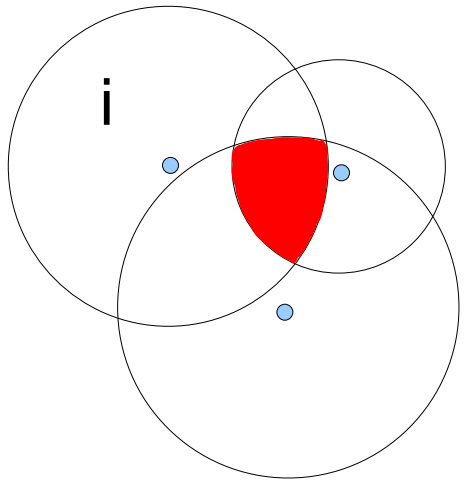


Figure 4.2: The shaded region is a Steiner Zone of degree 3 and is denoted $SZ(3)$. It is the intersection of three disks.

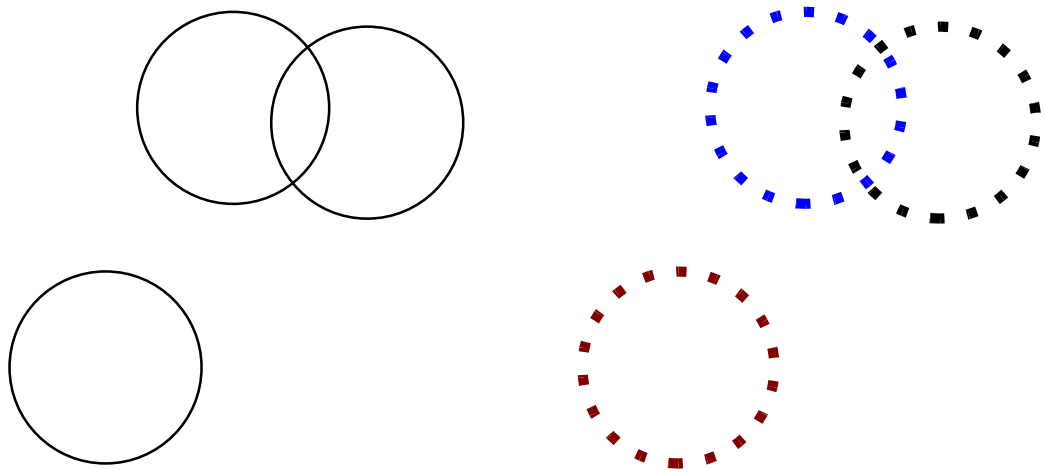
We illustrate the CETSP in Figure 4.1. In the standard TSP shown in Figure 4.1(a), the salesman leaves home (the start node is depicted by a rectangle), visits four nodes, and returns home. In the CETSP shown in Figure 4.1(b), the salesman needs to get within distance r_i of each node i (this is depicted by the four disks which, in this example, all have the same radius). If the salesman visits the location at the overlap of the four disks, then each node has been visited. Clearly, the out-and-back solution to the CETSP has a shorter total length than the optimal TSP solution.

A Steiner zone (SZ) of degree k, $SZ(k)$, is the non-empty intersection of k disks where each disk can have a different radius. Any point inside a Steiner zone simultaneously visits all k of its member nodes. We show this in Figure 4.2.

In Chapter 2, we developed a three phase Steiner-zone heuristic to solve the CETSP. We generated 48 test problems and compared our best heuristic (SZ2) to several methods, including a genetic algorithm (GA) from Silberholz and Golden



(a) Original CETSP

(b) Each disk is approximated by $k = 18$ evenly spaced points.

Figure 4.3: The GTSP tour must visit one of the $k = 18$ points in each cluster (circle).

[67]. The GA solves a generalized TSP (GTSP) approximation of the CETSP. In the most common definition of the GTSP, a salesman must visit exactly one node from each of the m clusters of nodes in the cheapest way. The GTSP can solve a discrete approximation of the CETSP. The perimeter of each disk in the CETSP is discretized by k points. Each disk's set of k points is designated a cluster. The depot is a one-node cluster. After the GTSP is solved, we take the solution found by the GA and further reduce the distance by adjusting the location of the visited point for each disk while maintaining the sequence of clusters found by the GA. In Chapters 2 and 3 we let $k = 24$ and called this method GTSP2 and GTSP-VRP. A GTSP approximation of three disks and a solution to a 100-node problem is illustrated in Figures 4.3 and 4.4. The solution in Figure 4.4 is an example of the GTSP1 heuristic described in Chapter 2. When Phase III is applied to the tour sequence found by GTSP1, the result is an example of GTSP2. In Figure 4.4, the GTSP1 tour length

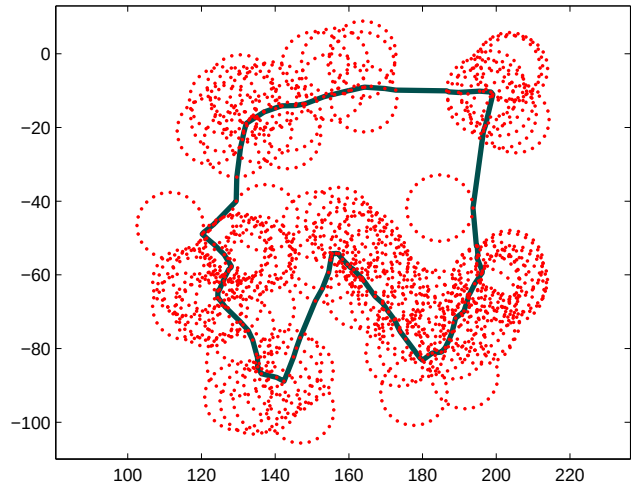


Figure 4.4: A $k = 24$ GTSP approximation of a 100-node CETSP and the solution found by the GA (about 311).

is approximately 311 and the GTSP2 tour length is almost 308.

In Chapter 2, we found that when there is a low or moderate overlap of disks, GTSP2 consistently produced tours up to 11% shorter than SZ2. GTSP2 was very slow, averaging about 1.1 million CPU seconds to solve each problem (the largest took months to solve). The smallest GTSP instances had 100 clusters (2,400 points), and the largest instances had 1,000 clusters (24,000 points), plus a depot. SZ2 solved the same CETSP problems in an average of 1.601 CPU seconds per problem. For the remainder of this chapter, SZH refers to all variants of our heuristic (SZ1, SZ2, SZVRP1, SZVRP2, SZVRP3, SZVRP4) that were discussed in Chapters 2 and 3.

The chapter is organized as follows. In Section 5.2, we review the literature on performance analysis of local search algorithms along with the literature on relevant problems. In Section 4.3, we study the tours found by Silberholz and Golden's GA to motivate the development of our new heuristics. In Section 4.4, we describe a variant of SZH called the minimum-angle heuristic, and in Section 4.5 we describe

the Phase IV post-processor for SZH. We summarize the results in Section 4.6 and give conclusions in Section 5.7.

4.2 Literature Review

Although local search heuristics are ubiquitous in modern algorithms, little rigorous comparison of their performance in actual implementations has been published. Johnson and McGeoch [47] compared many implementations of a large number of local search heuristics including two-opt, three-opt, and nearest-neighbor, for the symmetric TSP. They found that, implementation details aside, the performance of a simple heuristic such as two-opt varies greatly. For example, on large, structured problems (up to 100,000 nodes), two-opt generally produced solutions 5% to 20% from optimality. For random instances between 1,000 and 10,000 nodes, two-opt generally produced tours 60% to 120% from optimality.

Some authors have studied theoretical properties of greedy heuristics. Bang-Jensen et al. [11] and Gutin et al. [44] prove that, for certain types of problems, greedy methods not only perform poorly, they may actually produce the worst possible solution. Problems exhibiting this characteristic are called greedy-resistant. Bendall and Margot [12] give sufficient conditions for proving greedy resistance.

Lesh and Mitzenmacher [50] describe a general method for improving a solution generated by a greedy algorithm. Their Bubble Search methodology improves the solutions for a class of greedy algorithms known as priority algorithms. A *priority algorithm* organizes all elements of the problem according to a specified order func-

tion and places them according to a priority function. Using the nearest-neighbor (NN) heuristic for the TSP as an example, if node i was just inserted into the tour, NN orders all edges, e_{ij}, by length for all nodes j that have not yet been visited. The algorithm places the first edge in that order in the tour. For a *fixed priority* algorithm, the ordering function is applied exactly once and the highest-priority element remaining in the ordering is the next one placed. For an *adaptive priority* algorithm, the ordering may change after a certain number of placements. As with fixed priority algorithms, the highest-priority element in the ordering is always the one that is placed next.

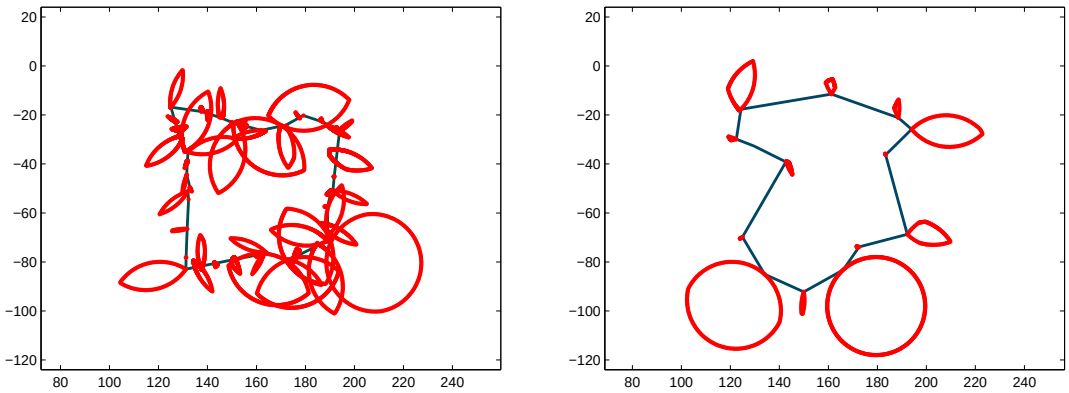
Lesh and Mitzenmacher extend the idea of prioritization to the *anytime priority* algorithm. The algorithm is run for for multiple orderings, returning the best solution found. For each new ordering, however, a different priority vector is used. Given an ordering, each element chooses the kth highest-priority remaining choice, where k is different for each element. For example, given a 5-node TSP (excluding the depot) solved by NN, and a priority vector $3, 4, 1, 2, 1$, do the following. The first node to be inserted in the tour chooses the third closest node as its neighbor, the second node inserted chooses the fourth closest remaining node, the third node chooses its closest remaining neighbor, and so on. The authors' Bubble Search formalizes the process of choosing different priority vectors to effectively search the solution space close to an incumbent solution.

Sarkar et al. [62] describe the Lookahead Search algorithm. A greedy algorithm deterministically explores only one complete solution whereas an exact algorithm such as branch-and-bound implicitly examines the entire solution space.

They point out that many combinatorial optimization problems can be modeled as a tree search where the leaves are all feasible solutions and the intermediate nodes at depth k are partial solutions with k of the n elements fixed.

Using the tree search paradigm, Sarkar et al. define a compromise between exact algorithms and greedy algorithms. In a greedy algorithm, starting at the root node of the tree, the next node is chosen using only local information available at that level. At a given node in the tree, Lookahead Search looks ahead k levels. It is guaranteed to produce results no worse than the strictly greedy method. Each lookahead subproblem is solved by the same greedy algorithm as the root node problem. If $k = n$, then the entire solution space is explored and optimality is assured. If $k = 0$, the algorithm is strictly greedy. The authors prove that even a $k = 1$ lookahead results in tighter bounds on solution values than the strictly greedy approach. For some problems, looking ahead only one level produces significantly better results. Solving the Euclidean TSP with the nearest neighbor (NN) heuristic, looking ahead one level at each node improved roughly 10% over the NN heuristic with no lookahead on a range of randomly generated TSPs up to 100 nodes.

Two problems that are highly relevant to our work in this chapter are the GTSP and the Angular-Metric TSP. Silberholz and Golden [67] define the current state of the art for the GTSP. The authors develop a genetic algorithm using a modified rotational ordered crossover operator (mrOX) along with local optimization routines such as two-opt improvement. The mrOX operator considers a large number of possible sequences before selecting one to be the new child. Their solutions averaged only 0.03% above optimal for the standard GTSP test problems with



(a) Steiner zones produced by the GA (b) Steiner zones produced by SZH

Figure 4.5: Two different solutions to the 2D, fixed-radius, Euclidean norm team2_200 problem. The GA's solution has many more Steiner zones than the SZH solution. Consequently, the average Steiner zone degree is much lower for the GA solution than the Steiner-zone solution.

$n \leq 442$ and known optimal solutions. For problems with $442 \leq n \leq 1084$ and unknown optima, their solutions equaled or bettered all best-known solutions.

The notion of a tour's *total angle cost* plays an important role in the improvements to SZH developed in this chapter. Aggarwal et al. [5] define the total angle cost of a tour to be the sum of the direction changes at the nodes in the tour. They describe the Angular-Metric TSP (AMTSP), in which the objective is to minimize the total angle cost. They present an approximation algorithm that runs in $O(\log n)$ time. Applications for the AMTSP include trajectory planning for high-speed aircraft as well as route planning for robots with high inertia. High-speed aircraft and high-inertia robots are both objects that cannot turn quickly, requiring a route that minimizes the total amount of turning.

4.3 Motivation

In Chapters 2 and 3, we described the three phases of SZH in detail. Phase I reduces a graph of n nodes to m Steiner zones. Phase II assigns a point to represent each Steiner zone and sequences these points as a TSP tour (CETSP) or as a set of VRP routes (CEVRP). Phase III minimizes the length of each tour by moving the point representing each Steiner zone.

Phase I of SZH is greedy. We order all n nodes in a list using one of four different ordering functions [50], closest-to-depot, furthest-from-depot, closest-to-centroid, and furthest-from-centroid (recall that SZH consists of four separate runs of the Phase I - Phase II - Phase III cycle, one for each of the four ordering functions). We choose the first remaining node, i, and construct all the Steiner zones that we find with the remaining nodes in the list. We set aside the Steiner zone of highest degree found and remove its member nodes from the list. This process is repeated until the list is empty. The result is a set of m Steiner zones where m is no larger than n and potentially much smaller. Some Steiner zones may have very high degree. A high-degree Steiner zone is the intersection of a large number of disks and is typically very small in area. This illustrates the trade-off inherent in SZH. SZH reduces problem size, sometimes quite dramatically. However, the feasible area for any member node in a high-degree (typically small area) Steiner zone is greatly restricted. For example, in Figure 4.5(b), 200 nodes were reduced to 13 Steiner zones, a substantial reduction in problem size. The high degree Steiner zones are very small, though, and force the solution tour to go out of the way to visit them.

4.3.1 Steiner Zones and the Genetic Algorithm

Given a feasible CETSP tour sequence produced by any heuristic, we can create a set of Steiner zones (not unique) on which the tour is built. In Figure 4.5, we show the Steiner zones found by SZ2 and GTSP2 for a 200-node problem. The solution found by SZ2 contains many fewer Steiner zones than the solution found by GTSP2.

In Table 4.1, we show the highest-degree Steiner zone found by SZH (specifically, SZ2) and GTSP2 for the 48 fixed-radius, 2D, Euclidean test instances given in Chapter 2 along with the largest possible degree Steiner zone that exists for each problem. In Table 4.2, we show the number of Steiner zones found by each method for the same problems. The maximum-possible-degree SZs were found using Circu-

(a) Result with a larger-degree SZ

(b) Result with a smaller-degree SZ and a singleton SZ

Figure 4.6: An illustration of better results using more Steiner zones. The depot is at the bottom right.

lar Trapezoidal Decomposition, denoted CTD, which is described in Appendix F. In 39 of the 48 problems, the highest-degree SZ found by GTSP2 is less than or equal to that found by SZ2 (often four to five times so). As a result, GTSP2 solutions tend to have a substantially larger number of Steiner zones than SZ2 solutions. In problems where lower-degree Steiner zones produce better solutions, the global search space explored by the GA enables it to find these solutions. SZH does not find those solutions because its search space is restricted to the m high-degree (very small in area) Steiner zones that it created from n nodes. The more the graph is reduced in Phase I, the smaller the solution space becomes. Compared to GTSP2, SZH is more likely to become stuck in a local minimum. Figure 4.6 demonstrates how a solution with more Steiner zones can be shorter than a solution with fewer Steiner zones. In Chapter 2, we found that GTSP2 consistently found better tours than SZH for problems with low or moderate levels of disk overlap. This suggests that any improvements to SZH should focus on finding solutions with more lower-degree Steiner zones.

In Figure 4.7, we employ a visual analogy to explain why GTSP2 performs better than SZH. We call this figure an *elevation map*. We create the map by overlaying graph G with a mesh grid (100 x 100), calculating the number of disks that contain each mesh point (the degree of the mesh point), and plotting the degree on the z-axis. Some regions contained by more than one disk might not contain any grid points. To ensure we sample every single intersection of disks, we include in the elevation map the centroid of every region found by CTD for G.

Now, assume Figure 4.7 represents a topographical map of an area to be visited

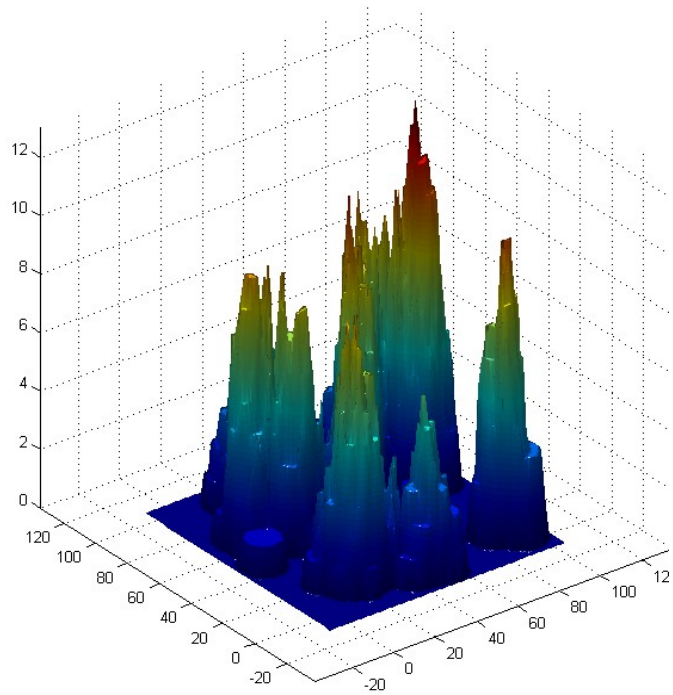

Figure 4.7: Elevation map for a 100-node CETSP. Overlap ratio is 0.08 (moderately low).

by a hiker. The hiker wants to visit (approach within r units) each of the n points of interest that have been identified. Using SZH to plan the route, the hiker would summit many of the steepest peaks (Steiner zones of large degree) since many points are visited simultaneously at the peaks. To visit the remaining nodes, the route produced by SZH might then lead the hiker to visit many of the deepest valleys (Steiner zones of small degree), resulting in a tour with substantial elevation change - an exhausting hike. If, on the other hand, the hiker used the GA to plan the route, the tour would tend to stay at the middle elevations, exhibiting a substantially lower total change in elevation. The route would not visit many peaks and could avoid most valleys. This hike would be much less arduous than the hike planned by SZH.

Our modifications to SZH attempt to create solutions with similar change-in-

elevation properties (low average Steiner zone degree) to the GA's solutions without the GA's extremely large computation times. We hope that the solution space of the CETSP is such that the local minimum initially found by Phases I through III of SZH is in roughly the same solution space as the improved solution we want to find. If this assumption holds, then by finding a good initial solution quickly using SZH, it should not be difficult to quickly move to the improved solution. This would accomplish our goal of combining the best aspect of simple, greedy algorithms (speed) and the best aspect of metaheuristics (accuracy).

4.4 Limiting Steiner Zone Degree

4.4.1 Maximum Degree

The naive way to minimize the degree of the Steiner zones found by SZH is to place an upper limit, u, on degree for all Steiner zones. We found that many of the same SZs found when $u = \infty$ may be constructed. For example, a $SZ(30)$ found when $u = 35$ may now exist as four different Steiner zones, for $u = 8$. Preliminary tests confirmed that placing an explicit upper limit on Steiner zone degree rarely found better solutions than the standard SZH heuristics. Choosing a good value for u was pure guesswork and the results did not exhibit any patterns that would help determine better values for u.

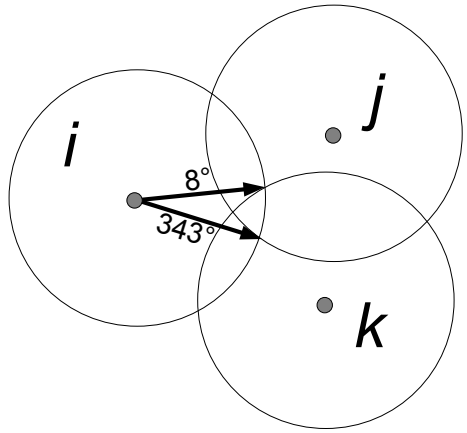

Figure 4.8: The base node is i. Only the lower (343°) and upper (8°) angles of intersection are required to specify the $SZ(3)$ formed by $disk(i)$, $disk(j)$, and $disk(k)$.

4.4.2 Minimum Angle of Intersection

A smarter method of limiting the degree requires a good conceptual understanding of Steiner zones. A Steiner zone of degree k is characterized by a node of origin (base node) and two polar angles of intersection relative to the base node. This is illustrated in Figure 4.8 for an SZ(3). We refer to the absolute value of the difference in the two angles as the total angle of intersection. A larger total angle of intersection between two disks implies a larger amount of overlap between the disks. A Steiner zone with a large total angle of intersection has a relatively large area. Steiner zones of large degree have a very small total angle of intersection and a relatively small area. The small area of intersection leaves little flexibility in choosing a point to represent such a Steiner zone in Phases II and III. The minimum angle of intersection heuristic (MAH) places a lower bound, denoted by ang_{LB}, on the minimum total angle of intersection for a Steiner zone. We illustrate this in Figure 4.9 where the minimum angle of intersection is 50°. Any potential Steiner

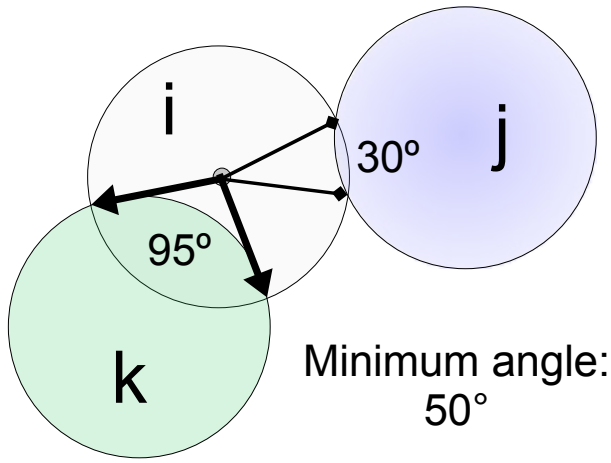

Figure 4.9: The total angle of intersection between node i and node k is 95°. SZ_{ik} is created. The total angle of intersection between node i and node j is $< 50°$. SZ_{ij} is not created.

zones whose total angle of intersection is less than ang_{LB} are not created. As ang_{LB} increases, MAH chooses Steiner zones that restrict the solution space less and less. MAH produces Steiner zones whose average degree is less than or equal to that of SZH. We hope to find a good value or range of values for ang_{LB} where the solution quality is similar to GTSP2. We note that when $ang_{LB} = 0°$, MAH is equivalent to SZH. When $ang_{LB} = (360 - \epsilon)°$, for ϵ near zero, all Steiner zones will have degree 1 (this is equivalent to the LK-SOCP and CW-SOCP heuristics described in Chapters 2 and 3, respectively).

4.5 Phase IV Post-Processor

Rather than searching for a good value or range of values for ang_{LB}, we use the solution found by Phases I through III of SZH as a starting solution which we modify to lower the average Steiner-zone degree. Let the current solution contain

the sequence of nodes i-j-k. We define the *turn angle* for edge e_{ij}, denoted by α_{ij}, as the deviation from a straight line between consecutive edges e_{ij} and e_{jk}. If nodes i, j, and k are collinear, then e_{ij} and e_{jk} form a straight line and $\alpha_{ij} = 0°$. If e_{ij} and e_{jk} are perpendicular, then $\alpha_{ij} = 90°$, the maximum possible turn angle. If the angle between e_{ij} and e_{jk} is greater than 90°, say 130°, then $\alpha_{ij} = ((0-130)\ modulo\ 90)° = 40°$. We let the turn angle for a tour be the sum of α_{ij} for all edges e_{ij} in the tour.

The definition of turn angle does not accurately characterize whether the shape of a tour is simple or complex. A route may have a simple overall structure, for example, a square, but consist of numerous short segments, each making large turns. The tour in Figure 4.10 contains many 90° turns, but as a whole, the tour is square in shape. Although a square has a very simple geometric shape, the tour in Figure 4.10 would have a very high turn angle. To address this, we normalize each edge's turn angle by dividing it by the proportion of total route length contributed by that edge. That is, we multiply each e_{ij}'s turn angle by $\frac{d_{ij}}{tour\ length}$ where d_{ij} is the length of edge e_{ij}. The tour in Figure 4.10 has a relatively small normalized turn angle consistent with that of a simple shape such as a square.

Phase IV is a post-processor that can be applied to any CETSP or CEVRP solution that contains Steiner zones with degree greater than one. At each iteration of the Phase IV post-processor, we calculate each Steiner zone's normalized turn angle and sort the Steiner zones in descending order. We choose the 10% highest-turn angle Steiner zones and remove them from the route. For each $SZ(k)$ removed, we replace it with unique duples and singletons ($SZ(2)$ and $SZ(1)$) created from its k member nodes. For member node i, we find the closest remaining member node,

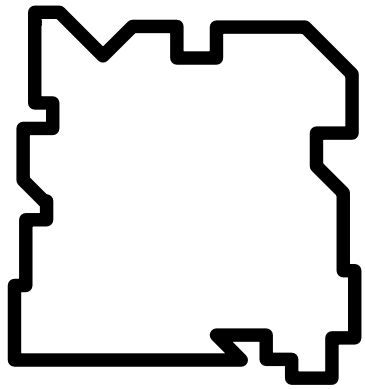

Figure 4.10: A nearly square route. It is a simple shape and should have a low turn angle. Without accounting for each edge's relative contribution to the tour length, however, the turn angle is very large.

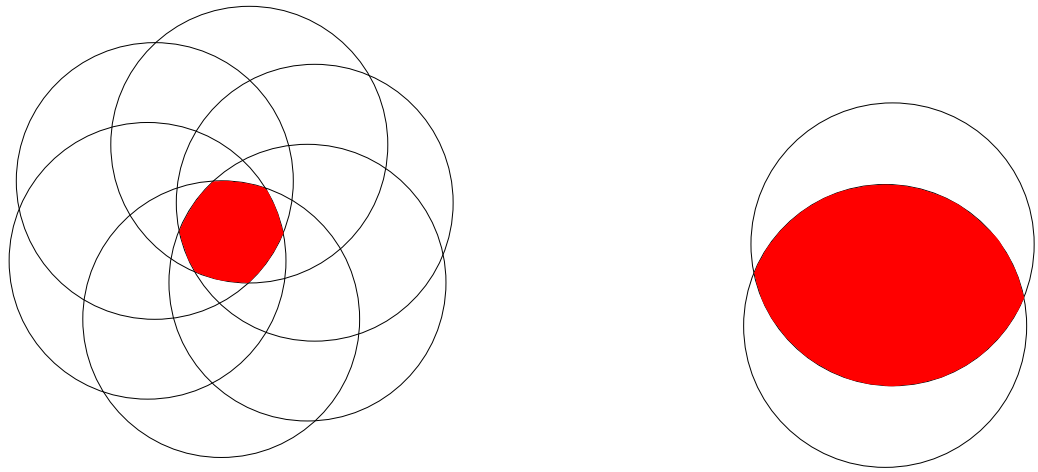
and create a duple. We select the closest member node in order to create Steiner zones with the most overlap area and provide more flexibility in placing each zone's representative point. We force every third new Steiner zone created to be a singleton. We tested other numbers such as every second or every fifth, but found that every third produced the shortest tours. The entire process for replacing one Steiner zone with duples and singletons created from its member nodes is illustrated for a $SZ(6)$ in Figures 4.11 through 4.14.

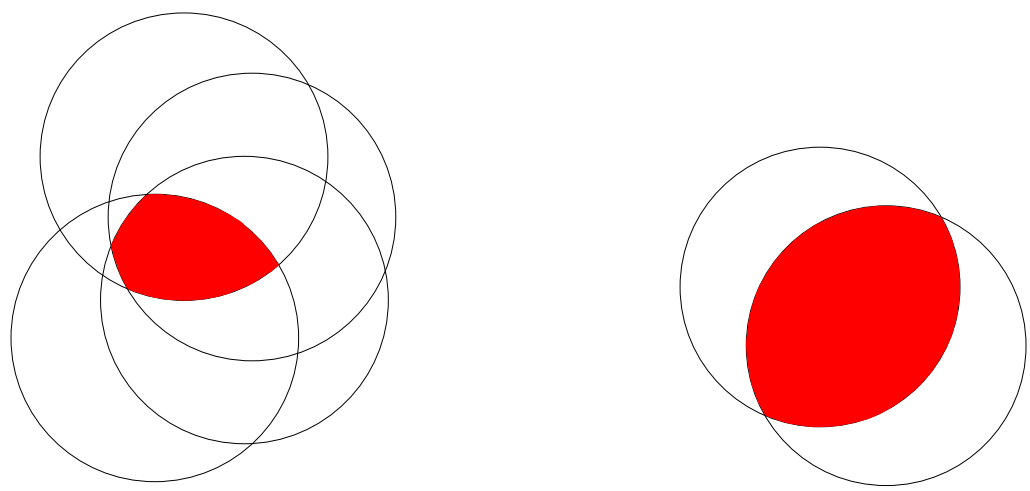
After replacing the top 10% highest-turn-angle Steiner zones with duple and singleton Steiner zones, unique feasible representative points for each of the new SZs are assigned using the method described in Chapter 2. Phase II and Phase III are reapplied to the route. Without assigning each new Steiner zone a representative point that is different from its previous one, the routing sequence could not change when Phase II is applied. The removal and replacement process is continued until four successive iterations produce no improvement in distance or the number of



(a) A $SZ(6)$ before applying Phase IV

(b) The first duple created

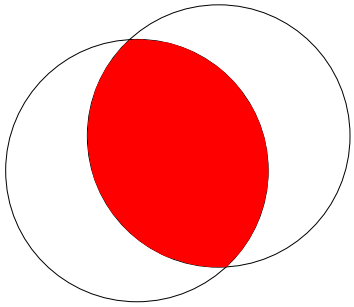
Figure 4.11: The Steiner zone in Figure 4.11(a) has degree 6. Remove one member node and create a duple with the closest of the other five member nodes. Set the duple aside.



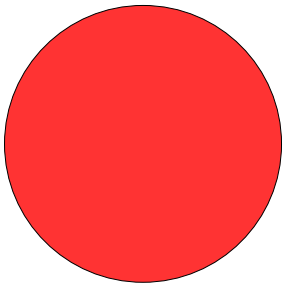
(a) The remaining $SZ(4)$

(b) The second duple created

Figure 4.12: A Steiner zone of degree 4 remains. Remove another node, create a duple in the same manner, and set it aside.

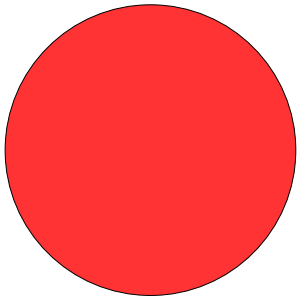


(a) The remaining $SZ(2)$

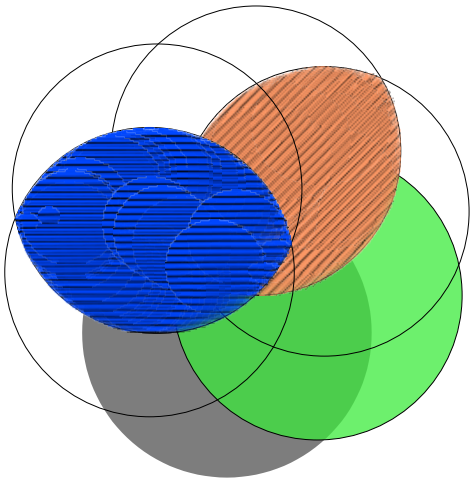


(b) Every third replacement must be a singleton

Figure 4.13: A duple is all that remains. Every third replacement, no matter the number of member nodes remaining, we automatically create a singleton. Set the singleton aside.



(a) A singleton remains



(b) Final result: four separate but overlapping Steiner zones

Figure 4.14: Only a singleton remains, so Phase IV for the original $SZ(6)$ is complete, having replaced one high-degree SZ with four low-degree ones. SZH now has more flexibility (a larger solution space) in which to find a good tour on these low-degree Steiner zones.

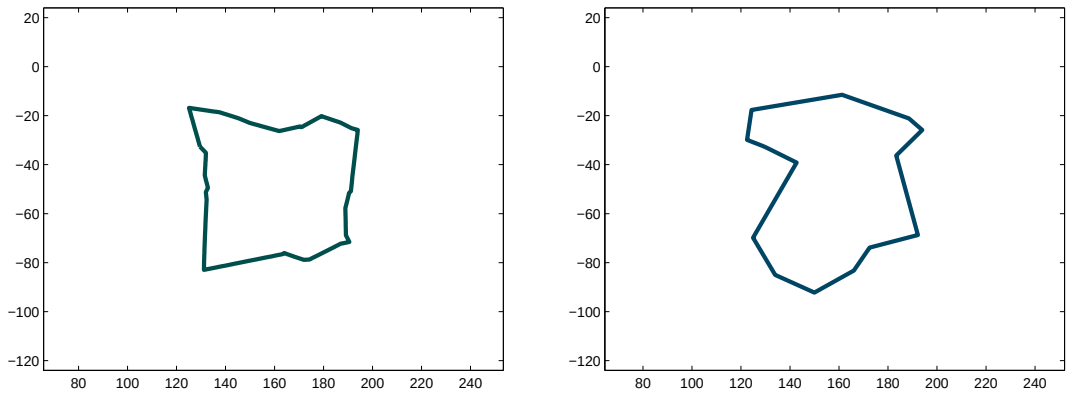
Steiner zones in the route is equal to the number of nodes in the problem, that is, no more Steiner zone replacements can occur.

We calculate the 10% number only at the beginning of Phase IV. For example, if Phase I reduced n nodes to $m = 10$ Steiner zones, then only one Steiner zone (10% of m) is removed from the solution at each iteration, even if n is relatively large compared to m. If we recalculated the 10% number at each iteration, then as the number of Steiner zones grows because of Phase IV replacements, the rate at which SZs are replaced grows faster. We found that recalculating can be twice as fast as not recalculating, but the results are usually slightly poorer.

After enough Steiner zones have been replaced by duples and singletons, there may be a large amount of Steiner-zone overlap. Because the IP_{PhIII} heuristic for Phase III works very poorly when there is substantial Steiner-zone overlap (see Appendix D), we solve Phase III to optimality using the second order cone program (SOCP) formulation described in Appendix E.

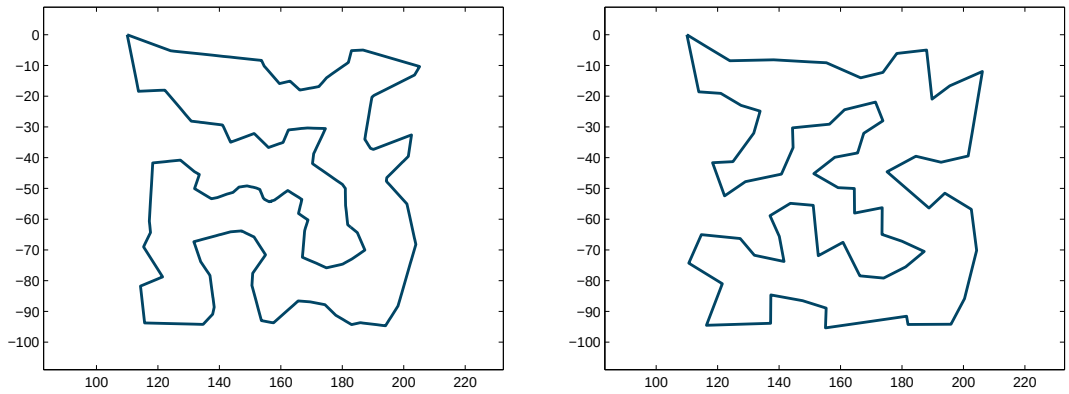
We expect that replacing a high-turn angle Steiner zone with many smaller ones will help the algorithm escape a local minimum and find routes with a simpler shape and a shorter distance. A route with a lower turn angle is not necessarily shorter than a route with a higher turn angle. However, in our experiments, we found that it typically is shorter.

In Figures 4.15 and 4.16, we show the tours found by SZH and the GA for two problem instances where the SZH solutions compare poorly with the GA solution (a 200-node moderate overlap problem and a 400-node low overlap problem). In both instances, the solution found by the GA has a much lower normalized turn angle



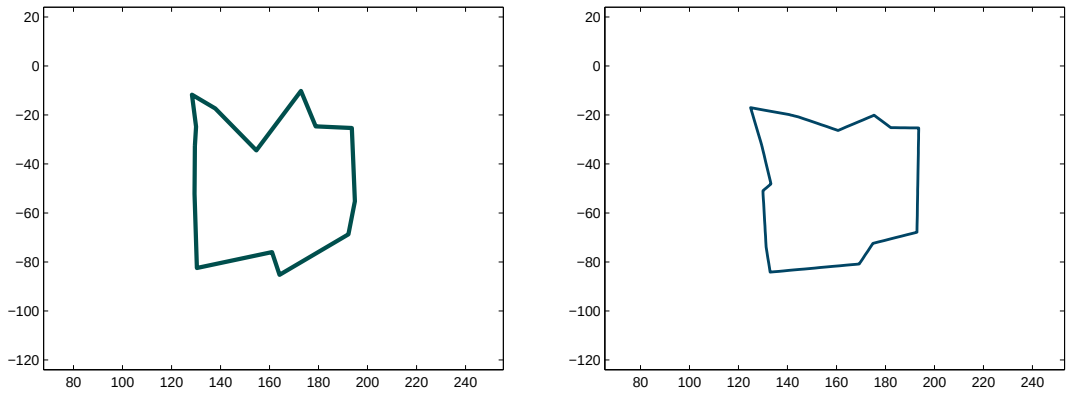
(a) GA solution (b) Steiner-zone solution

Figure 4.15: Solutions to a 200-node CETSP. The GA solution (249.9) is 11% shorter than the Steiner-zone solution (277.6) and has a simpler geometric shape. The SZ solution shape is not simple because the small, high-degree Steiner zones created in Phase I constrain the shape.



(a) GA solution (b) Steiner-zone solution

Figure 4.16: Solutions to a 400-node CETSP. The GA solution (680.0) is 9% shorter than the best Steiner-zone solution (742.8). It is difficult to visually judge which route has the simpler geometric shape, but the GA solution has a lower route turn angle.



(a) A Steiner-zone solution before post-processing

(b) After post-processing

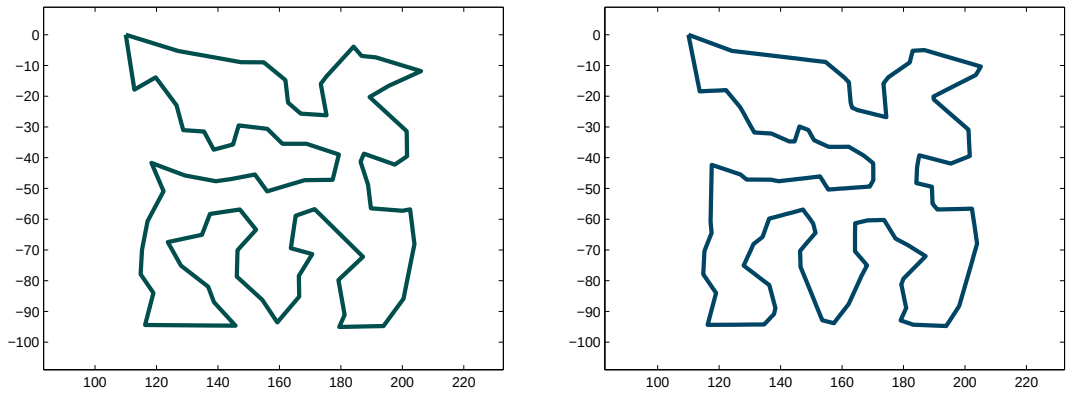
Figure 4.17: The route in (a) is about 284 and is not the best Phase III solution to this 200-node problem. After applying Phase IV, the shape is very similar to the GA solution in Figure 4.15(a). The tour length is about 250, only 0.11% longer than the GA solution.

than SZH.

In Figures 4.17 and 4.18, we show the SZH solutions to both problems before and after applying the Phase IV processor. Applying Phase IV usually produces smoother-looking tours which are shorter. GTSP2 solved the two problems in 34,768 CPU seconds and 276,264 CPU seconds, respectively. SZ2 solved them in 0.718 CPU seconds and 1.296 CPU seconds. When the Phase IV post-processor is applied to the SZ2 solutions, the times increase to 7.704 CPU seconds and 32.594 CPU seconds, respectively. In these examples, the post-processor adds a substantial amount of time to SZ2, but it is still several orders of magnitude faster than the GA.

4.5.1 Phase IV and MAH

The ideas behind MAH and the Phase IV post-processor can easily be combined. We can apply Phase IV to the results found by MAH for a range of values



(a) A Steiner-zone solution before post-processing

(b) After post-processing

Figure 4.18: The route in (a) is about 747 and is not the best Phase III solution to this 400-node problem. After applying Phase IV, many of the corners have been smoothed out and the distance is now about 688. This is only 1.27% longer than the GA solution.

for ang_{LB}.

4.5.2 Phase IV and the CEVRP

We developed two variants of the Phase IV heuristic for the CEVRP. In one method, VRP-based Phase IV, a maximum of one Steiner zone is replaced in each route per iteration of Phase IV. We expect that the VRP-based Phase IV will allow the solution to evolve gradually in each iteration. The limit on the number of Steiner zones per iteration means that Phase II is solved more often, allowing the VRP solver to potentially find a very good solution. A second method, which we call TSP-based Phase IV, treats each route as if it were a stand-alone CETSP. That is, for route k, we replace up to 10% of its Steiner zones per Phase IV iteration. With TSP-based Phase IV, our goal is to improve the initial set of VRP routes locally as much as possible without significantly altering the structure of the solution. We

expect that the underlying set of VRP routes to remain relatively similar after each iteration of TSP-based Phase IV.

4.6 Computational Results

In Chapter 2, we tested two variants of SZH (SZ1, SZ2) and 13 heuristics on 48 2D Euclidean CETSP problems. Across all problems, we found that SZ1 and SZ2 produced the best combination of speed and accuracy. For low and medium overlap ratio $TSPLIB$ problems, however, GTSP2 was substantially more accurate than SZ1 and SZ2, and for six of the seven high overlap $TSPLIB$ problems, LK-SOCP was much more accurate. In Chapter 3, we tested four variants of SZH (SZVRP1, SZVRP2, SZVRP3, SZVRP4) and four heuristics on the same 48 problems (converted to CEVRPs). We found that SZVRP2 produced the best combination of speed and accuracy with SZVRP3 and SZVRP1 performing nearly as well. However, for medium and high overlap problems, CW-SOCP typically produced the best solutions.

In this chapter, we compare results produced by MAH, the Phase IV post-processor, and the combined $\text{MAH}_{PhaseIV}$ to the results of the best methods from Chapters 2 and 3.

4.6.1 CETSP Heuristics

We coded 11 heuristics for comparison purposes including four heuristics described in Chapter 2: SZ1, SZ2, GTSP2, and LK-SOCP. GTSP2 and LK-SOCP are

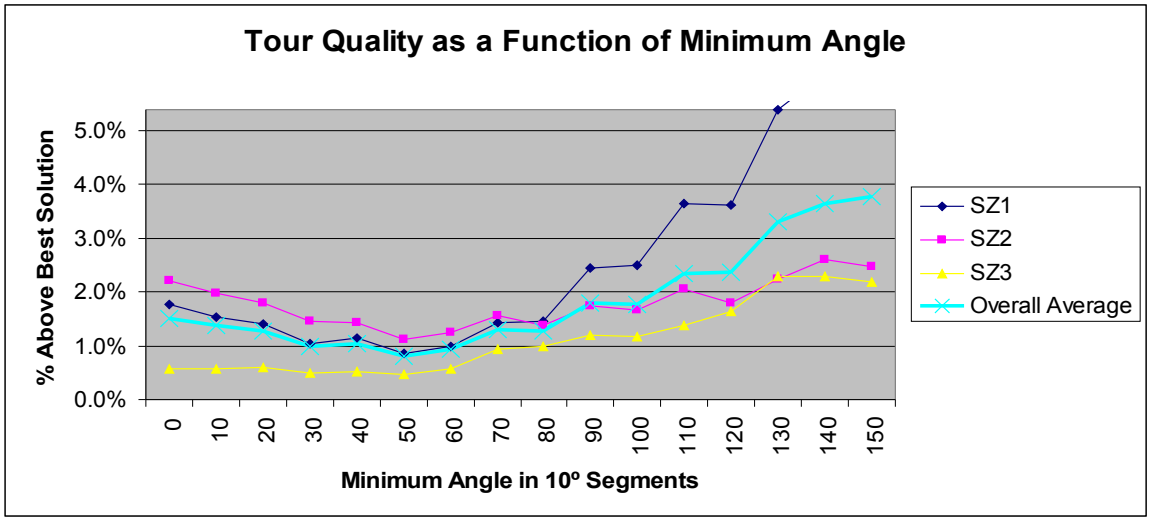


Figure 4.19: Letting ang_{LB} equal each of the integer values in [50°, 59°] produces the best set of solutions, on average, for $SZ1_{0-360}$, $SZ2_{0-360}$, and $SZ3_{0-360}$ across all Euclidean problems.

included because they performed better than any SZH method on specific classes of problems in Chapter 2. We coded four new heuristics using the methods described in this chapter: $SZ1_{0-359}$, $SZ2_{0-359}$, SZ3, and $SZ3_{0-359}$. SZ3 is the same as SZ2 except that the Phase IV post-processor is applied. $SZ1_{0-359}$ and $SZ2_{0-359}$ are two implementations of the MAH heuristic. $SZ3_{0-359}$ implements the $MAH_{PhaseIV}$ heuristic. They are the same as SZ1, SZ2, and SZ3 except that they are run 360 times, setting ang_{LB} equal to each of the integer values in [0°, 360°]. We include results for the best 10° ranges (over all problems) for $SZ1_{0-359}$, $SZ2_{0-359}$, and $SZ3_{0-359}$. For example, the best average deviation for $SZ1_{0-359}$ over a 10°range over all 48 problems is 50°-59°, as shown in Figure 4.19. We refer to this as $SZ1_{50-59}$. The best of the 10 solutions from this range is reported for each problem. The same idea applies to $SZ2_{50-59}$ and $SZ3_{50-59}$.

The tour-length results for the 11 heuristics on the 48 test problems are given

in Table 4.6.1. The average deviations from the best solutions in Table 4.6.1 are given in Table 4.6.1. Columns in both tables are ordered by the overall average deviation from best (left) to worst (right).

The results in Tables 4.6.1 and 4.6.1 are quite different from the results in Chapter 2. In Chapter 2, we saw that GTSP2 was clearly the most accurate method for low and medium overlap ratio $TSPLIB$ problems, finding best solutions for 12 of 14 problems. LK-SOCP was the best method for high overlap ratio $TSPLIB$ problems (if we removed the result for *pcb*442), averaging only 0.10% deviation from the best solution. In Table 4.6.1, the results are different. GTSP2 finds only six of 14 best solutions for low and medium overlap ratio $TSPLIB$ problems while $SZ3_{0-359}$ finds eight best solutions. $SZ3_{0-359}$ finds all seven best solutions for high overlap ratio $TSPLIB$ problems. Over all 48 problems, $SZ3_{0-359}$ finds 37 best solutions. SZ3 finds solutions as good as or better than GTSP2 26 times and finds solutions as good as or better than LK-SOCP 45 times. $SZ2_{0-360}$ equals or improves GTSP2 27 times and LK-SOCP 48 times.

The average deviation from the best solutions has also changed. In Chapter 2, we saw that the Steiner-zone methods averaged about 4.50% deviation from the best for low overlap ratio $TSPLIB$ problems and about 7.00% for medium overlap ratio $TSPLIB$ problems. For the same problems, $SZ3_{0-359}$ averages 0.99% and 0.16% and SZ3 averages 2.22% and 2.73%, respectively. For the high overlap ratio $TSPLIB$ problems, both $SZ3_{0-359}$ and SZ3 average 0.00% deviation. Over all 48 problems, $SZ3_{0-359}$ averages 0.41% deviation, and three methods ($SZ3_{50-59}$, SZ3, $SZ2_{0-359}$) average less than 2%.

In Table 4.6.1, we give the computation times for the 11 heuristics on the 48 problems. Columns are ordered from fastest (left) to slowest (right). In Chapter 2, we saw that LK-SOCP was the fastest method overall, with SZ1 a close second. GTSP2 was extremely slow. The current rankings remain the same. We see that three heuristics ($SZ2_{50-59}$, $SZ1_{50-59}$, SZ3) average between 20 and 28 seconds over all problems while $SZ3_{50-59}$ averages 169.225 seconds over all problems. Although much slower than LK-SOCP and SZ1, these four methods are still orders of magnitude faster than GTSP2.

Based on the computational experiments with the 48 problems using the 2D Euclidean norm, we observe the following. (1) SZ3 appears to be the best variant of SZH. If we consider the column orderings in Tables 4.6.1 and 4.6.1 to be algorithm rankings, then SZ3 and $SZ3_{50-59}$ have the best combination of speed and accuracy, having average ranks of 3.5 and 4.5, respectively. Obtaining a high-quality initial solution quickly and then escaping the local minimum (by relaxing the set of Steiner zones in search of a lower tour turn angle) improves accuracy with only a moderate increase in computation time. Combining that idea with the idea of encouraging moderate-degree Steiner zones with a minimum angle-of-intersection produces an accurate algorithm. (2) GTSP2 is the most accurate method for low overlap ratio problems; it is no longer the most accurate method for medium overlap ratio problems. Interestingly, GTSP2 finds the best solution for all five *concentrCircles* problems but does poorly on most of the other *GEOMETRIC* problems. (3) $SZ1_{0-360}$ and $SZ1_{50-59}$ are slower than their SZ2 counterparts which is different from the computation times reported in Chapter 2. This is because the IP_{PhIII}

solver used by the SZ1 variants does not perform well when there is a moderate or large amount of Steiner-zone overlap, as noted in Appendix D. As ang_{LB} increases, the Steiner zones found in Phase I have more overlap, causing IP_{PhIII} to slow down and produce poorer results. (4) The MAH, Phase IV, and $\mathrm{MAH}_{PhaseIV}$ algorithms improve the accuracy of SZH. Most increase computation time by only a small amount. For example, the best SZH method averages less than 1% deviation for low overlap ratio $TSPLIB$ problems (previously the best SZH method averaged 4.58%). The best SZH method averages 0.16% deviation for medium overlap ratio $TSPLIB$ problems (previously the best SZH method averaged 6.44%). The most inaccurate of the new methods, $\mathrm{SZ1}_{50-59}$, still improves on SZ2 by over 1%. (5) The MAH and $\mathrm{MAH}_{PhaseIV}$ variants can easily be parallelized, applying p different processors to p different values of ang_{LB} simultaneously. Quad-core and eight-core computers are available, and 16-core computers will become available soon. With such increased computing power at hand, $\mathrm{SZ3}_{50-59}$ could easily be as fast as SZ3.

Table 4.3: Tour lengths for 11 heuristics on 48 problems with equal radius and 2D Euclidean norm

4.6.2 CEVRP Heuristics

We coded 15 SZH heuristics for comparison purposes including one heuristic described in Chapter 3, SZVRP3. SZVRP3 is included because it had one of the best average performance rankings of the eight heuristics tested in Chapter 3. We coded 14 new heuristics: eight Phase IV heuristics, four MAH heuristics, and two Phase IV + MAH heuristics. SZVRP1$_{50-59}$, SZVRP2$_{50-59}$, SZVRP3$_{50-59}$, SZVRP4$_{50-59}$ are MAH heuristics. They are the same as SZVRP1, SZVRP2, SZVRP3, and SZVRP4 except that they are run 10 times, for ang_{LB} equal to each integer value in [50°, 59°]. We chose this range because it performed best of all 10° ranges for the CETSP. SZVRPk_t and SZVRPk_v are Phase IV heuristics for SZVRP1, SZVRP2, SZVRP3, SZVRP4. t indicates that TSP-based Phase IV is applied. v indicates that VRP-based Phase IV is applied. SZVRP2$_{t\ 50-59}$ and SZVRP3$_{t\ 50-59}$ are two Phase IV + MAH heuristics. The variants of SZVRP1 and SZVRP2 that apply Phase IV solve Phase III to optimality. SZVRP1 and SZVRP2 without Phase IV apply the IP$_{PhIII}$ heuristic to solve Phase III, but as noted earlier, IP$_{PhIII}$ cannot be used to solve Phase IV.

In order to fit the CEVRP results into presentable tables, we use "SZV" for "SZVRP" in Tables 4.6 - 4.8.

Table 4.6: Tour lengths for 15 heuristics on 48 CEVRP problems with equal radius and 2D Euclidean norm

	$SZV3_{t\ 50-59}$	$SZV3_t$	$SZV4_t$	$SZV4_v$	$SZV3_v$	$SZV2_{t\ 50-59}$	$SZV4_{50-59}$	$SZV3_{50-59}$	$SZV2_{50-59}$	$SZV2_t$	SZV3	$SZV2_v$	$SZV1_{50-59}$	$SZV1_t$	$SZV1_v$

In Table 4.6, we present the results for the 15 heuristics on the 48 CEVRP problems with equal radius and 2D Euclidean norm. We see that $\text{SZV3}_{t\ 50-59}$ produces 28 best solutions, SZV3_t produces eight best solutions, and SZV4_t produces six best solutions.

In Table 4.7, we give the average deviation (as a percentage) from the best solution in Table 4.6 for each problem. $\text{SZV3}_{t\ 50-59}$ averages less than 1% deviation for every category of 48 problems and has an overall average deviation of 0.59%. In Chapter 3, we saw that SZV3 had the best overall average deviation of 3.02%. This represents a substantial improvement in accuracy. All heuristics except for variants of SZVRP1 average less than 5% deviation. SZVRP1 variants average over 7% deviation.

For each of the SZVRPk Phase IV variants, TSP-based Phase IV produced better average deviations than VRP-based Phase IV. For example, SZV2_t averages 4.09% deviation and SZV3_v averages 4.74%. The differences are not large but are consistent. As k grows from 1 to 4, the difference in average deviation between $\text{SZVRP}k_t$ and $\text{SZVRP}k_v$ shrinks suggesting that the quality of the Phase II VRP solver affects the performance of the VRP-based Phase IV methods more than it affects the quality of TSP-based Phase IV methods.

Table 4.7: Percentage deviation from the best solution for 15 heuristics on 48 CEVRP problems with equal radius and 2D Euclidean norm

In Table 4.8, we give the computation times for the 15 heuristics. We see that eight methods need less than 100 CPU seconds on average to solve the test problems. $\text{SZV3}_{t\ 50-59}$ requires almost 1500 seconds to solve a problem. Variants of SZV1 and SZV2 are generally faster than variants of SZV3 and SZV4. This is consistent with the results in Chapter 3. For each k from 1 to 4, $\text{SZV}k_v$ is faster than $\text{SZV}k_t$. As k increases, the gap in computation time decreases. For example, SZV1_v is almost four times faster than SZV1_t, but SZV4_v is only twice as fast as SZV4_t. This decrease is not as substantial as the reduction for average deviations given in Table 4.7.

If we consider the column orderings in Tables 4.7 and 4.8 to be performance rankings, then SZV3_t is the best heuristic with an average rank of 5.5 followed by SZV3_v with an average rank of 6.5.

Table 4.8: Computation time (CPU seconds) for 15 heuristics on 48 CEVRP problems with equal radius and 2D Euclidean norm

	$SZV1_v$	$SZV1_{50-59}$	$SZV2_v$	$SZV1_t$	SZV3	$SZV2_t$	$SZV2_{50-59}$	$SZV3_v$	$SZV3_t$	$SZV2_{t\ 50-59}$	$SZV3_{50-59}$	$SZV4_v$	$SZV4_t$	$SZV4_{50-59}$	$SZV3_{t\ 50-59}$

4.7 Conclusions

We developed a post-processing phase of the Steiner-zone heuristic, called Phase IV, that systematically replaces Steiner-zones in an attempt to find a better solution with a lower total angle cost. We presented a variant of SZH, called the minimum angle heuristic (MAH), that enforces a lower limit on the total angle of intersection allowed in order for a Steiner zone to be created. Combining the Phase IV post-processor with MAH produced a third variant, $\text{MAH}_{PhaseIV}$. The three heuristics can be applied to both the CETSP and the CEVRP.

We tested all three methods on the same benchmark problems used in Chapters 2 and 3. We found that the Phase IV post-processor and $\text{MAH}_{PhaseIV}$ improved the accuracy of SZH. Applying MAH or $\text{MAH}_{PhaseIV}$ for a range of only 10° increased the computation time a reasonable amount, as did applying only Phase IV. Methods that previously found better tours than SZH for certain classes of problems (GTSP2, LK-SOCP, CW-SOCP) are now either not as good as or do not consistently outperform SZH.

We applied these our heuristics to the same problems using the Manhattan norm and found similar results (see Appendix A). In future work, we will develop cooperative parallel methods using SZH to solve the CETSP and CEVRP.

Chapter 5

The Sequence-Dependent Team Orienteering Problem

5.1 Introduction

The classical Vehicle Routing Problem (VRP) is one of the most well-studied problems in the operations research literature due to its very practical nature. Given a depot and a set of n nodes, k vehicles must visit all nodes in the cheapest (usually distance or time) manner such that each node is visited exactly once and the vehicles begin and end their routes at the depot. Additional constraints such as time limits and minimum delivery amounts can be imposed to make the VRP useful in practice. Orienteering problems are part of a group of VRP variants known as profit-maximizing VRPs (see Feillet et al. [35]). In the sport of orienteering, a person is given a set of locations to visit such that at every point visited, the participant receives a certain reward or profit. There is a time limit, so not all points can be visited. When the participant is part of a team, more points can be visited in the same amount of time and thus a larger profit obtained. Substituting vehicles for team members, we have the Orienteering Problem (OP) and the Team Orienteering Problem (TOP).

A related problem is called the Linear Ordering Problem (LOP). We are given a set of n nodes and a profit matrix P, such that p_{ij} is the profit received for ordering i before j. In the LOP, we order the set of n nodes such that the sum of p_{ij} over i

and j is maximized.

We present a new combinatorial optimization problem with practical application that is related to the VRP, TOP, and LOP. Given a profit matrix, P, where p_{ij} is the profit received for visiting i before j, the Sequence-Dependent Orienteering Problem (SDOP) and the Sequence-Dependent Team Orienteering Problem (SD-TOP) are orienteering problems in which the profit for visiting node i is dependent on the entire ordered sequence of visited nodes. For all visited nodes, h, preceding i, there is a profit p_{hi}, and for all visited nodes, j, following i, there is a profit of p_{ij}. There is an element of bin-packing in this problem since we want to visit as many nodes as possible in order to increase the total profit.

In order to evaluate the objective function, we combine all routes into one meta-route. The meta-route is the list of all visited nodes sequenced by arrival time, from first to last. Making small changes in the sequence of nodes, such as switching the order of two nodes, can cause large changes in the objective function. Similarly, switching a node from one vehicle to another can cause large changes to the ordered sequence, which in turn can cause large changes in the objective function. Unvisited nodes are not counted in the objective function. In the remainder of the paper, we refer to team members as vehicles and call both the single-vehicle and multiple-vehicle versions of the problem the SDTOP.

For example, consider the 10-node problem whose P is given in Table 5.1. There are two homogeneous vehicles, one depot, d, and the current routes are:

- Route 1: d-1-4-5-d

Table 5.1: Example profit matrix

	1	**2**	**3**	**4**	**5**	**6**	**7**	**8**	**9**	**10**
1	0	4	9	3	1	10	7	6	1	5
2	2	0	3	1	8	5	1	5	3	7
3	0	6	0	7	1	5	6	3	1	2
4	1	10	7	0	5	1	3	1	2	3
5	10	9	1	2	0	0	6	10	3	8
6	7	6	9	8	3	0	2	8	2	2
7	4	10	9	6	8	7	0	4	1	9
8	7	3	7	10	0	4	6	0	8	4
9	4	7	8	4	2	4	9	7	0	2
10	5	5	3	3	9	6	8	8	8	0

- Route 2: d-9-2-6-7-d.

To evaluate the objective function, we combine the routes into one meta-route:

- Meta-route: d-1-9-2-6-7-4-5-d.

Summing all p_{ij} in the meta-route, for i preceding j, we obtain an objective function value of 101. Suppose that node 4 is moved from its current position in route 1 and placed after node 5 in the same route. This change results in the set of routes and meta-route:

- Route 1: d-1-5-4-d
- Route 2: d-9-2-6-7-d
- Meta-route: d-1-9-5-2-4-6-7-d.

Evaluating the meta-route, the objective function value is now 75, approximately 25% less than before, even though we have made only one, intra-route move. This kind of disproportionate change in objective function value for a small change in the routes is atypical in the classical VRP or OP but is commonplace in the SDTOP. The change in objective function value is amplified as the problem size grows.

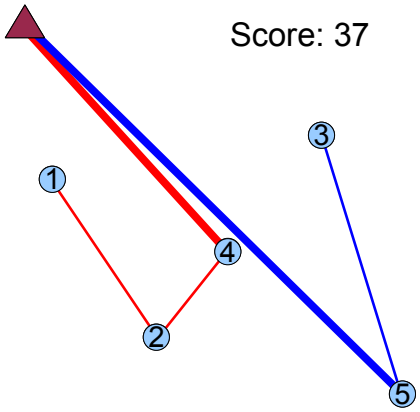
Table 5.2: Profit matrix for Figure 5.1

	1	**2**	**3**	**4**	**5**
1	0	-2	8	2	-9
2	2	0	3	-1	-6
3	-8	-3	0	13	-14
4	-2	1	-13	0	9
5	9	6	14	-9	0

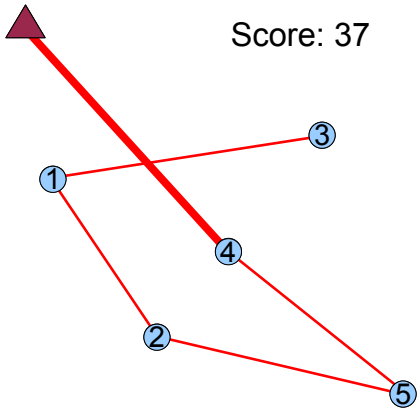
In Figure 5.1 and Table 5.2, we illustrate how the presence of additional vehicles does not guarantee a larger objective function. For two vehicles, the optimal ordering is $4-5-2-1-3$. Thus, we add $(p_{42}+p_{45}+p_{41}+p_{43})+(p_{52}+p_{51}+p_{53})+(p_{21}+p_{23})+(p_{13})=37$. For three vehicles, the optimal ordering is 4-2-5-1-3. Subtracting p_{52} from 37 and adding in p_{25}, we get 27. In general, if it is not true that $p_{ij}=-p_{ji}$ for all i and j and each row of P has at least some positive values, then if the optimal solution for k vehicles leaves at least one node unvisited, it is likely that the optimal solution for $k+1$ vehicles will have a better objective function value than that of the k-vehicle solution. If all nodes are visited in a k-vehicle solution, then the $k+1$-vehicle solution may or may not produce a better objective function value. This is true for any P.

When matrix P is replaced by a vector p whose i^{th} component, p_i, represents the profit for visiting node i, SDTOP becomes the TOP. When one vehicle has enough capacity and there is no maximum tour length, SDTOP reduces to the LOP.

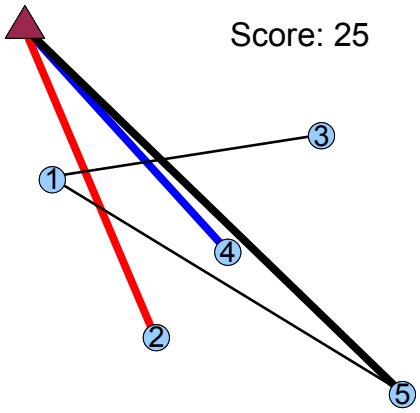
The SDTOP can be applied to problems in aerial reconnaissance. Given a set of potential targets to observe and limited resources such that all targets may not be visited, there may be a different benefit for visiting target i before target j than for



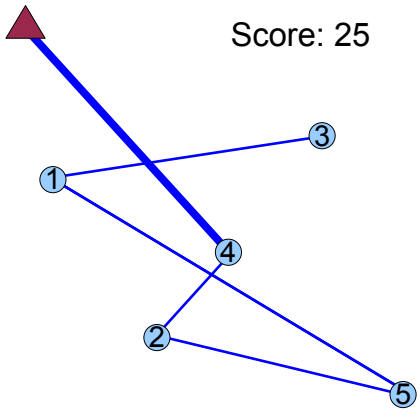
(a) Optimal solution with two vehicles required



(b) Meta-route for solution in (a)



(c) Optimal solution with three vehicles required



(d) Meta-route for (c)

Figure 5.1: More vehicles do not necessarily produce better objective function values. The triangle is the depot. Edges departing the depot are thicker than others. Edges returning to the depot are not shown.

visiting j before i. The intelligence available at target j may be much less valuable if j is observed after target i [56, 59].

In the rest of this chapter, we review the literature relevant to orienteering problems. We formulate the SDTOP as a mixed-integer program. We develop a record-to-record (RTR) travel algorithm to solve the SDTOP which can handle additional side constraints. We test our algorithm on many problem instances and find that our algorithm produces high-quality solutions.

5.2 Literature Review

Many authors discuss problems similar to the SDTOP. O'Rourke et al., Richards et al., Shetty et al., Moser, and Porto [56, 59, 64, 54, 58], described below, study variants of the unmanned aerial vehicle (UAV) routing problem in which target priorities are important. These articles collectively demonstrate that it is reasonable to model the UAV routing problem letting the objective function determine the order in which targets are visited based on pairwise priorities.

O'Rourke et al. [56] use a tabu search algorithm to dynamically route UAVs. They suggest a possible modification of their problem in which a priority scheme is added to the targets. They state that, in some cases, a subsequence of targets to visit may be fixed so that a consecutive image pass of these targets can be made.

Richards et al. [59] study a UAV routing problem that couples task allocation and trajectory planning. They allow for pairwise time dependencies, where target i must be visited after target j.

Shetty et al. [64] solve a static UAV routing problem with a heterogeneous fleet. That is, the targets are determined beforehand and do not change during the mission. They maximize the total weighted service (amount of bombs dropped) to the targets subject to service level bounds, capacities (a UAV's bomb payload), and distances. The service weights are based on predetermined priorities.

Moser [54] discusses the scheduling and routing of tactical aerial reconnaissance vehicles where each target is assigned a priority designation of highest, high, routine, etc. (using equivalent nonnegative integer values). He formulates the problem as an orienteering problem in which the total benefit to the route planners (the total sum of priorities) is maximized.

Porto [58] describes a UAV routing problem where targets must be re-imaged a certain number of times. Each target is given a priority level. A weighted combination of a target's priority level and the size of its area represents the target's value. The cumulative value is maximized using evolutionary programming. In his model, individual UAV routes cannot be evaluated independently. Routes are aggregated into a single solution for evaluation.

The problem in the literature most similar to the SDTOP is the Target Visitation Problem (TVP), a bi-objective problem introduced by Grundel and Jeffcoat [41]. The TVP can be thought of as an LOP with a second objective of minimizing tour length. That is, a single vehicle visits all n nodes, trying to minimize distance and simultaneously maximizing profit. Profit is defined as in the LOP and SDTOP; a profit p_{ij} is received if i is visited before j. The total profit is the sum of all pairwise profits.

Grundel and Jeffcoat's work was not meant to be a thorough computational study but rather an introduction to the problem. They consider a one-vehicle version of the problem and provide a simple Greedy Randomized Adaptive Search Procedure (GRASP) to solve the TVP. GRASP works by constructing a number of feasible solutions in two phases. In the constructive phase, solutions are built node by node, randomly selecting each node from an ordered candidate list. In the local optimization phase, heuristics such as 2-OPT are used to find a local optimum for each solution. The final solution is the best local optimum. Grundel and Jeffcoat use their heuristic to compare TVP objective function values with pure TSP and pure LOP versions for each test problem.

Arulsevan et al. [10] [9] present two random-keys genetic algorithms (GAs) to solve small instances of the TVP. Random-keys is a method of encoding TSP tours as chromosomes that ensures feasible solutions are always produced. Each allele of a chromosome is represented by a random number, typically between 0 and 1. The node in the tour corresponding to the ith allele is equal to the rank index of the ith allele in an ordered list of alleles. For example, consider a 5-node problem and a chromosome that looks like {0.63, 0.12, 0.29, 0.97, 0.06}. An ordered list of these five numbers, (0.06, 0.12, 0.29, 0.63, 0.97), implies that the corresponding tour is Depot-4-2-3-5-1-Depot since 0.63 has rank index 4 in the ordered list, 0.12 has rank index 2, etc.

Arulsevan et al.'s second genetic algorithm is the same as the first except that a 2-exchange local optimization is performed on every offspring produced by the crossover operator. They tested both methods on 25 problems ranging from 8 to

16 nodes and compared the average solution time and performance over 250 runs with that of the optimal solution found by solving a mixed-integer linear program (MILP) with CPLEX. On these small problems, both GAs performed extremely well, finding the optimal solution over 99% of the time with very fast solution times.

The literature on the VRP is vast and comprehensive. We refer the reader to books edited by Toth and Vigo [68] and by Golden et al.[38] and to the bibliography by Cordeau et al. [21]. The TOP was first introduced by Chao et al. [16] and continues to be studied today [6]. Similarly, the LOP has received substantial attention in the literature. Charon and Hudry [18] developed the noising method and used it within a branch-and-bound framework to solve the LOP for weighted tournaments. They solved thousands of LOPs with as many as 100 nodes to optimality. For all but six problems, the noising method found the optimal solution quickly. A second run of the noising method found the optimal solution to the remaining six problems.

5.3 Definitions

We say that matrix P is inverse symmetric if $p_{ij} = -p_{ji}$ for all i and j. Otherwise, P is generalized. If P is inverse symmetric, then $p_{ij} + p_{ji} = p_{ij} - p_{ij} = 0$. In order to evaluate the objective function, we order all visited nodes by arrival time, first to last. This sequence is called a meta-route, a route with infinite maximum route length and capacity.

If nodes i and j have arrival times less than ϵ units apart, we call these simultaneous arrivals. If i and j are visited simultaneously, what profit should we receive

(p_{ij}, p_{ji}, both, neither)? We decided that neither p_{ij} nor p_{ji} should be counted. However, p_{ik} and p_{jk} are counted for all k such that k is visited after i and j. If P is inverse symmetric, we can count both p_{ij} and p_{ji} (they cancel each other out), and the question of simultaneous arrivals becomes irrelevant. The formulation presented in Section B.1 does not consider simultaneous arrivals. It is much simpler than the alternative formulations given in Appendix K.

5.4 Formulating the SDTOP

In this section, we formulate the SDTOP as a MILP. We have a homogeneous fleet where k_{max} vehicles are used. To simplify the formulation, denoted by SDTOP$_{simp}$, we assume that there are no simultaneous arrivals (within ϵ). If this assumption does not hold, SDTOP$_{simp}$ could return an erroneous result. Even with randomly located points, there is no guarantee that simultaneous arrivals will not occur. In Appendix K, we present two alternative formulations for the SDTOP that are more complex than SDTOP$_{simp}$. SDTOP$_{general}$ identifies simultaneous arrivals, and SDTOP$_{noSimul}$ explicitly forbids them from happening. In both models: (1) each vehicle may have different beginning and ending depots, and one vehicle's depots may be different from the others', (2) each vehicle may have different capacity and route-length constraints, and (3) we may impose a minimum number and a maximum number of the available vehicles to use in a solution (we do not specify which vehicles to use).

All three models can include time window constraints. In some situations, it

may make sense that no two nodes can be visited within a certain period of each other. That is, we want no simultaneous arrivals for $\epsilon \gg 0$. Both formulations in Appendix K can model this situation, SDTOP$_{general}$ with a hard constraint and SDTOP$_{noSimul}$ awarding neither p_{ij} nor p_{ji} when the arrival times are less than ϵ units apart. Finally, we note that more than one solution with an optimal objective function value, opt^*, may exist. To find the minimum distance optimal solution, we add a constraint requiring that the objective function equal opt^*, change the objective function to minimize total distance, and solve the model again.

The meta-route sequence is not modeled explicitly in any of the formulations. It must be implied from the sequencing of arrival times (not vehicle-by-vehicle but across all vehicles in the solution). We use $4N(N-1)$ variables to accomplish this.

5.4.1 Variables and Constants

<u>Constants</u>: ($i \neq j$)

- N - number of possible nodes, excluding the depot (node 0)
- K - total number of vehicles available (indexed by k)
- P - profit matrix
- p_{ij} - profit received for visiting i before j
- q_i - demand at node i
- Q - vehicle capacity
- s_i - service time required at node i; $s_0 = 0$ by definition
- T - time or distance matrix (any distance norm is allowed)
- t_{ij} - travel time or distance between i and j

- T_{max} - maximum tour length
- ϵ - cutoff value for simultaneous arrivals; if two arrival times are less than ϵ units apart, they are considered simultaneous

<u>Variables</u>: $(i \neq j)$; $i > 0$ and $j > 0$ unless otherwise specified.

- $x_{ijk} = 1$ if vehicle k travels from node i to node j; 0 otherwise
- $y_{ik} = 1$ if node i, for $i \geq 0$, is visited by vehicle k; 0 otherwise
- $w_i = 1$ if node i is visited in general; 0 otherwise
- a_i is the time that node i, for $i \geq 0$, is visited; if node i not visited, a_i is forced to any number in $[0, N\epsilon]$
- $\delta_{ij} = a_j - a_i$; difference in arrival times
- $z_{ij} = 1$ if i's arrival time is before or simultaneous with j's time
- $\alpha_{ij} = 1$ if both i and j are visited; 0 otherwise
- $\beta_{ij} = 1$ if both i and j are visited and i's arrival time is before or simultaneous with j; 0 otherwise

5.4.2 SDTOP$_{simp}$

$$w_i + w_j \leq 1 + \alpha_{ij} \qquad \forall\ i \geq 1,\ j \geq 1 \tag{5.12}$$

$$-(\alpha_{ij} + z_{ij}) \leq -2\beta_{ij} \qquad \forall\ i \geq 1,\ j \geq 1 \tag{5.13}$$

$$\alpha_{ij} + z_{ij} \leq 1 + \beta_{ij} \qquad \forall\ i \geq 1,\ j \geq 1 \tag{5.14}$$

$$a_i + x_{ijk}(T_{max} + (s_i + t_{ij})) \leq T_{max} + a_j \qquad \forall\ k;\ i \geq 0,\ j \geq 1 \tag{5.15}$$

$$-a_i + x_{ijk}(T_{max} - (s_i + t_{ij})) \leq T_{max} - a_j \qquad \forall\ k;\ i \geq 0,\ j \geq 1 \tag{5.16}$$

$$a_i + w_i(s_i + t_{i0} - T_{max}) \leq 0 \qquad \forall\ i \geq 1 \tag{5.17}$$

$$\sum_{i \in S, j \in S} x_{ijk} \leq |S| - 1 \text{ for } S \subseteq \{1, \ldots, N\},\ 2 \leq |S| \leq N \qquad \forall\ k \tag{5.18}$$

$$0 \leq a_i \leq T_{max} \qquad \forall\ i \geq 1$$

$$-T_{max} \leq \delta_{ij} \leq T_{max} \qquad \forall\ i \geq 1,\ j \geq 1$$

$$\alpha_{ij},\ \beta_{ij},\ w_i,\ x_{ijk},\ y_{ik},\ z_{ij} \in \{0, 1\} \qquad \forall\ i, j, k$$

The objective function (5.1) sums the pairwise profits, p_{ij}, for every pair of nodes that is visited such that i is visited strictly before j. Constraints (5.2) and (5.3) require that the depot be visited at time zero by all vehicles. Without (5.2), a_0 can be positive if it leads to an improved objective function value. This is invalid. Since w_i is binary, constraint (5.4) requires that every node is visited, if at all, by exactly one vehicle. w_i is a book-keeping variable and only included to help with readability. Constraint (5.5) guarantees that vehicle capacity is not violated. Constraints (5.6) and (5.7) are the flow-balance constraints requiring node i, if it is visited, to have exactly one predecessor and one successor. Constraints (5.15) and (5.16) fix the arrival times for all visited nodes. Groër et al. [40] pointed out both that (5.15) eliminates subtours and (5.16) could be dropped if we wanted to allow vehicles to wait at node i. They showed that adding some of the standard subtour elimination constraints in (5.18), with cardinality no larger than $N/2$, produces faster solution times. Constraint (5.17) ensures that the total time for a route is feasible. (5.17) forces the arrival times for unvisited nodes to zero.

Constraints (5.8) to (5.14) are specific to the SDTOP. Constraint (5.8) stores the difference in arrival times between nodes i and j and is included to make the formulation easier to read. Constraints (5.9) and (5.10) force z_{ij} to 1 if j's arrival time follows i, even if j was not visited. In constraints (5.11) and (5.12), α_{ij} is forced to 1 if and only if both i and j are visited. Constraints (5.13) and (5.14) tie all the binary variables together by requiring β_{ij} to be 1 if and only if i and j are both visited and i's arrival precedes j's. This allows the objective function to include only the correct p_{ij} values since β_{ij}, then α_{ij}, then w_i and w_j, and finally y_{ik} and y_{jk} will all be pushed towards one by the objective function.

5.5 Heuristic

We use a record-to-record travel (RTR) algorithm [30], based on the implementation described in Groër [39] to solve the SDTOP. RTR works in uphill and downhill phases. During the uphill phase, any move that is no worse than some percentage (deviation) from the current best solution (record) is accepted. During the downhill phase, only strictly improving moves are accepted. The uphill phase runs for a fixed number of iterations while the downhill phase ends only when no improving move has been found. After a series of uphill and downhill moves are made, the solution may be perturbed and the entire process repeated.

Candidate moves are generated by seven local optimization procedures -- one-point-movement, two-point-movement, three-point-movement, two-opt, three-opt, or-opt, and cross-exchange. These procedures are described in [39]. The RTR

algorithm in [39] is initialized with a solution produced by a modified Clarke-Wright savings procedure. The k nearest neighbors for each node are stored for use in the local optimization routines. Rather than consider every possible move for node i, we consider only the moves that can be made with the k nearest neighbors of node i. After each series of uphill and downhill moves are finished, the solution is perturbed using the procedure described in Mester and Bräysy [51]. Given nodes i, j, k, l, and m, and edges i-j-k, we search for an edge l-m such that the α-weighted change in total route distance for inserting node j between l and m is minimized. The insertion cost is: $(c_{ij} + c_{jk} - c_{lm}) - \alpha(c_{lj} + c_{jm} - c_{ik})$. This perturbation does not consider the resulting change in the value of the SDTOP objective function. By finding a new and potentially good VRP search neighborhood (which can mean fitting more nodes into our solution routes), we hope to find a better SDTOP neighborhood.

Our implementation considers a heterogeneous fleet where a minimum number and a maximum number of the K available vehicles may be specified. We ensure that the initial solution produced by the modified Clarke-Wright procedure is feasible. All nodes that are not in the current solution are placed in a route (which we call route 0) with infinite capacity and tour length. After any move is made such that we are no longer using the maximum allowable number of vehicles, we attempt to add one or two unrouted nodes to the empty route(s) even if the total profit decreases. Total profit can only decrease for a generalized matrix P such that at least one $p_{ij} < 0$ (P is easily transformed to ensure all $p_{ij} > 0$ by adding a large-enough constant) or if P is inverse symmetric. The optimal $k + 1$-vehicle solution is not necessarily better than the optimal solution with k vehicles. However, we found that

having more nodes routed generally provides a better chance of eventually finding a solution with higher total profit.

As noted earlier, small changes in the meta-route sequence can cause very large changes in the objective function value. Because of this, it is difficult to escape a poor solution neighborhood simply by switching the position of a few random nodes as in Mester and Bräysy [51] and Groër [39]. After a specified number of iterations, if any nodes are unrouted (route 0 is non-empty), we randomly choose a route, remove all nodes from this route, and set them aside. We try to place one or two nodes from route 0 into the now-empty route and apply one-point-movement to pack the route in the most profitable manner possible. The nodes that were set aside are then assigned to route 0. We refer to this procedure as Remove-Route-Shakeup.

5.5.1 Efficient Evaluation of the Objective Function

We found that over 99% of computation time was spent evaluating the objective function. In order to accurately calculate the value of the objective function, we must know the entire meta-route sequence. We call the potential solution being considered the candidate solution. We call the solution that is currently in place the current solution. For any candidate move, we must calculate all node arrival times that would change and create the candidate meta-route by sequencing the nodes by arrival time from first to last. Then we sum the relevant p_{ij}.

There is no shortcut around calculating new arrival times in any routes affected by a move. For example, suppose we have a single route with node sequence 1-2-3-4-

5. If we swap nodes 3 and 2, we obtain the sequence 1-3-2-4-5. a_1 does not change, a_2 and a_3 do change, and the arrival times for all nodes (4 and 5) that follow nodes 2 and 3 may or may not change. In order to create an accurate candidate meta-route, we must calculate new arrival times for node 2 and all nodes that follow it in its candidate solution route.

Similarly, suppose the current solution consists of two routes, 1-2-3-4-5 and 6-7-8-9-10. If we remove node 3 and place it after node 7, we obtain two new routes, 1-2-4-5 and 6-7-3-8-9-10. a_1, a_2, a_6, and a_7 do not change, a_3 does change, and the arrival times for all remaining nodes possibly change. In order to create an accurate candidate meta-route, we must calculate the new arrival times for node 3 and all nodes that follow 3 in its current route and its candidate route.

After the new arrival times have been calculated, we compute the new meta-route sequence. This can be done efficiently using a k-merge sort. Using a placeholder for each of the k routes, at each iteration, we append to the meta-route the node pointed to by the placeholder with the earliest arrival time and increment the placeholder one node forward in its route. When all k placeholders have reached the end of their respective routes, the meta-route has been ordered. Nodes not visited in the candidate solution are not included in the sort.

For example, let $k = 2$ with two candidate routes 4-1 and 3-5. Let the candidate arrival times in vector format be [10,-,5,2,7] (node 2 is not visited). The placeholder for each route is set at its first node. Node 4 is the first arrival, so node 4 is appended to the empty candidate meta-route. Route 1's placeholder is incremented and now points to node 1. Node 3 is the next arrival, so node 3 is ap-

pended to the candidate meta-route. Route 2's placeholder is incremented and now points to node 5. Node 5 is the third arrival, so node 5 is appended to the candidate meta-route. Route 2's placeholder is incremented past the end of route 2 so that route 2 is finished with the merge-sort. When only one route has nodes remaining to be merged, we add its remaining nodes in order. However, for illustration, we continue the example. The final arrival is node 1, so it is appended to the candidate meta-route which is 4-3-5-1. Route 1's placeholder is incremented past the end of route 1 so this route is finished. No visited nodes remain to be merged, and the sort is complete.

Once the candidate meta-route has been created, we evaluate the candidate objective function using Silberholz's HotnCold algorithm [66] (pseudocode for the algorithm is given in Appendix J). Any potential new objective function value is a function of the current value plus all new p_{ij}s minus all p_{ij}s that are no longer included. We must determine which p_{ij} should be added and which should be subtracted from the current objective function value. We define the set of hot nodes, HOT, to contain all nodes whose arrival times potentially change if the candidate move is accepted. Potentially is a key word since, for instance, in the example of route 1-2-3-4-5 becoming 1-3-2-4-5, it is possible that the arrival times for nodes 4, 5, or both, remain unchanged in the candidate solution. However, since node 4 and node 5 follow the nodes whose sequence changed, their arrival times potentially could change. They are considered hot nodes.

The set of cold nodes, $COLD$, contains all other nodes -- those whose arrival time remains unchanged if the candidate move is accepted. In the one-vehicle exam-

ple, if route 1-2-3-4-5 becomes 1-3-2-4-5, then HOT ={2, 3, 4, 5} and $COLD$ ={1}. In the two-vehicle example, if routes 1-2-3-4-5 and 6-7-8-9-10 become routes 1-2-4-5 and 6-7-3-8-9-10, then HOT ={3,4,5,8,9,10} and $COLD$ ={1,2,6,7}.

The HotnCold algorithm works as follows. Determine which nodes are in HOT and which are in $COLD$. Then, for each hot node, hot_i, in HOT, compare its arrival time against that of each cold node, $cold_j$, in $COLD$. If hot_i precedes $cold_j$ in the current meta-route but follows $cold_j$ in the candidate meta-route, subtract p_{ij} and add p_{ji}. Similarly, if hot_i follows $cold_j$ in the current meta-route but precedes $cold_j$ in the candidate meta-route, then subtract p_{ji} and add p_{ij}. Special attention must be paid to nodes that are visited in the candidate solution but are in the current solution's route 0. Similarly, special attention must be paid to nodes that are in the candidate solution's route 0 but are visited in the current solution.

After all comparisons between hot and cold nodes have been made, we do pairwise comparisons between all hot nodes. This can be done very efficiently when the move being considered is an intra-route move. This is because for any type of intra-route moves, we know which pairs of hot nodes i and j are currently ordered i before j but would have j before i in the candidate solution. For example, if we reverse a sequence of nodes in a route, all nodes currently sequenced before node j will now be sequenced after node j. For inter-route moves, we do not know this information, so every pairwise comparison must be made.

When the HotnCold algorithm finishes, we obtain the candidate objective function value. The HotnCold algorithm runs in $O(n^2)$ time but is fast in practice.

To illustrate the HotnCold algorithm, consider the profit matrix for the 10-

node SDTOP given in Table 5.1 along with the following routes and meta-route where node 5 is not visited and the objective function value is 179:

- Route 1: 6-10-2-1
- Route 2: 3-4
- Route 3: 9-7-8
- Meta-route: 6-3-9-10-7-8-2-4-1.

If we move node 1 to the second position in route 3, we obtain:

- Route 1: 6-10-2
- Route 2: 3-4
- Route 3: 9-1-7-8.

After calculating the new arrival times in Routes 1 and 2 (for nodes 1, 7, 8), we merge the three routes into the candidate meta-route. Given the current meta-route, we know that the arrival sequence and order of nodes 6-3-9 remains unchanged (although 10's new arrival time is unchanged, it is possible that node 1 would now precede node 10 whereas node 1 cannot precede nodes 6, 3, or 9). Therefore, we apply merge sort to the remaining nodes. The new meta-route is:

- Meta-route: 6-3-9-1-10-7-2-8-4.

Next, all nodes following node 1 in its current route (route 1) and its candidate route (route 3) could have new arrival times and belong in HOT. Therefore, $HOT = \{1, 7, 8\}$, and $COLD = \{6, 10, 2, 3, 4, 9\}$.

In the hot-to-cold comparisons, hot_1 now precedes $cold_{10}$, $cold_2$, and $cold_4$. hot_8 now follows $cold_2$. Therefore, add $p_{1,10}$, $p_{1,2}$, $p_{1,4}$, and $p_{8,2}$ and subtract $p_{10,1}$,

$p_{2,1}$, $p_{4,1}$, and $p_{2,8}$ to the current objective function value of 179. That is, $179 + 5 + 4 + 3 + 3 - 5 - 2 - 1 - 5 = 181$.

In the hot-to-hot comparisons, hot_1 now precedes hot_7 and hot_8. Therefore, add $p_{1,7}$ and $p_{1,8}$ and subtract $p_{7,1}$ and $p_{8,1}$. That is, $181 + 7 + 6 - 4 - 7 = 183$. Thus, the objective function value of the candidate solution is 183.

HOTnCOLD assumes that simultaneous arrivals do not occur. If they do occur, it is possible for the order in which two simultaneous-arrival cold nodes are stored to change when the data structure is sorted. If the order changes, the objective function of the potential move will be evaluated erroneously, perhaps allowing a move to be made that should not be made.

The nodes in many orienteering problems from the literature are geometrically arranged so that simultaneous arrivals occur frequently. In preliminary experiments, even after perturbing the coordinates, we encountered sporadic simultaneous arrivals. To evaluate a move in this situation, each time a potential move contains two nodes with simultaneous arrival times, i and j, we add a small, positive number to $t_{i-1,j}$, where node $i - 1$ is i's predecessor. When the RTR algorithm finishes, we restore the true edge distances and compute the true route distances.

5.6 Computational Experiments

There are no heuristics for solving the SDTOP in the literature. Obtaining exact solutions for even a 10-node problem has proven impractical. We solved one 10-node, 1-vehicle SDTOP in approximately 46,000 CPU seconds (we initialized

CPLEX with a very good solution). The root node LP relaxation for SDTOP$_{simp}$ is very weak and the default cuts that CPLEX applies tighten the lower bound very slowly.

5.6.1 Test Problems

Recently, Archetti et al. [6] published 130 new TOP problems based on 10 VRP problems from Christofides et al. [19]. Problems range from 51 to 200 nodes (including a depot) with various values for K (up to 20 vehicles) and Q for a total of 130 TOP problems. Some problem sets have randomly distributed nodes and some have highly clustered nodes. We created SDTOPS by generating an inverse symmetric P for each of the 10 data sets. The problems are divided into three sets.

For each of the 10 data sets, we created a single SDTOP which can be solved as an LOP using Charon and Hudry's code. In each problem, at least one vehicle can visit all N nodes in any order possible. Vehicles have different maximum tour length, maximum capacity, and starting and ending depots. We assigned each problem a unique generalized P matrix. We refer to these 10 problems as Set IV. We refer to the four sets of benchmark problems (140 total) collectively as the $SPERANZA$ problems. All problem data are given in Appendix M.

5.6.2 Parameters

In preliminary experiments, the RTR algorithm typically found its best solution for problems with fewer than 100 nodes in approximately 10 seconds, but the

larger problems sometimes found best solutions after hundreds of seconds of runtime. We chose 100 as a reasonable maximum computing time for each problem in our experiments. The local optimization parameter had three possible settings. In the first, we use all local optimization procedures (one-point movement, two-point movement, three-point movement, two-opt, three-opt, and or-opt) for the entire runtime. This is referred to as "All" in Table 5.3. In the second, we use all local optimization procedures only until we perform the first solution perturbation, after which we use only one-point movement and two-point movement. This is designated "All12" in Table 5.3. In the third, we use only one-point movement and two-point movement for the entire computation. This is designated "12Only".

The intensity parameter determines how many times the uphill phase of RTR is run before moving to the downhill phase. When applied to the VRP [15, 39], this is often set to 30. In preliminary testing, we found that large values of the intensity parameter consumed too much CPU time with little extra benefit. The initial deviation parameter sets the allowable deviation for all moves prior to the first perturbation. After the first perturbation, the deviation is set to 0.01 for the remaining RTR iterations. The neighbor list size parameter sets the size of the neighbor list used by the local optimization procedures. Helsgaun [45] found that the $k = 22^{nd}$ closest neighbor for one node appeared in the optimal solution of a 532-node TSP. Groër [39] used 25 as size of the neighbor list for his VRP algorithm. We tried three values for k, 10, 25, and 75.

The downhill cut-off parameter determines the number of perturbations that must be completed before we add the downhill phase to the RTR algorithm. For

example, if the parameter is set to three, then three cycles of the uphill phase and perturbation are completed before we include the downhill phase in the RTR algorithm. In our experiments, we used 0, 3, 4, and ∞ for this parameter.

The remove-route-shakeup parameter determines whether or not the Remove-Route-Shakeup procedure described in Section 5.5 is used. If yes, then we apply the procedure after 50 perturbations.

5.6.3 Creating SDTOP solutions from VRP solutions

We benchmark our solutions against a method (called VRP-SDTOP) that converts VRP solutions into SDTOP solutions. Given an SDTOP problem with a specified K, we solve the problem as a VRP using Groër's code [39], removing each node beforehand for which the maximum route length restriction is violated, even with an out-and-back route from the depot. When Groër's code is finished, it has stored up to the 200 best solutions found. For each of these 200 solutions, we do the following:

- Sort the routes by the number of nodes on each route. The number of routes may be larger than K so we want the K most-packed routes (routes that visit the most nodes). If matrix P is inverse symmetric, having more nodes in a solution is just as likely to worsen the solution as it is to improve it. For a generalized P, having more nodes cannot worsen the solution, as described earlier.
- Sort all routes having the same number of nodes by route length, from longest

to shortest. If the resulting SDTOP solution is used as a starting solution for local improvement procedures, then shorter routes are preferable to longer routes when the number of nodes is the same for each route.

- Choose the K most-packed feasible routes. If two routes visit the same number of nodes, choose the shorter route first.
- Create an SDTOP meta-route from the K routes, identifying all simultaneous arrivals to ensure the SDTOP objective function is evaluated correctly.
- Evaluate the SDTOP objective function for the meta-route.

The best of the 200 SDTOP objective functions is chosen as the result of VRP-SDTOP.

5.6.4 Finding an LOP solution to an SDTOP problem

As noted earlier, when at least one vehicle has large enough capacity and maximum tour length, the SDTOP reduces to the LOP. Charon and Hudry [18] have made their branch-and-bound code for solving the LOP on weighted tournaments available for public use. A weighted tournament is a directed acyclic digraph, but the profit matrix, P, for SDTOP is not. P is easily converted to such a graph by upper triangularization. Let P' be an upper triangular matrix whose elements, p'_{ij} for $j \geq i$, are equal to $p_{ij} - p_{ji}$. With P', we can use Charon and Hudry's code to find high-quality solutions to our problems in a fraction of a second, even for problems with hundreds of nodes. Given Charon and Hudry's reported results [18], it is reasonable to assume that their code produces excellent LOP solutions for our

Table 5.3: Parameter settings for nine variants of the RTR algorithm for solving the SDTOP

	(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)
Maximum Time	100	100	100	100	100	100	100	100	100
Local Optimization	All12	All12	All12	All12	All12	All12	All12	All12	All
Intensity	5	5	3	5	3	5	3	5	5
Initial Deviation	0.5	0.5	0.5	0.5	0.5	0.01	0.01	0.5	0.5
Size of Neighbor List	75	75	75	25	25	75	75	75	75
Downhill Cut-off	4	4	4	4	4	4	4	3	3
Remove-Route-Shakeup	Yes	No	Yes	Yes	Yes	Yes	Yes	Yes	Yes

problems.

We use the following substitute to test the quality of our RTR algorithm. In some problems (designated as Set IV below), we let $kMax > 1$, where at least one of the $kMax$ vehicles has large enough capacity and maximum tour length to solve the problem as an LOP. We obtain a high-quality LOP solution using Charon and Hudry's code and compare it to the multiple-vehicle solutions produced by RTR. If RTR does not find a solution that meets or exceeds the LOP solution value, then we cannot expect that it will do well on more complex problems. Without heuristics to compare against or tight lower bounds, we cannot make any stronger statements about the performance of our heuristic.

5.6.5 Results

We tried 70 different combinations of parameters described in Section 5.6.2 on the 140 $SPERANZA$ problems. For each problem, we let RTR run a maximum of 100 CPU seconds. In Table 5.4, we give the results for the nine best parameter settings on Set IV of the $SPERANZA$ problems. Column 2 is the best LOP solution produced by Charon and Hudry's LOP code (their code produces solutions in less than two seconds for our problems). Columns 3 through 12 are the results

produced by the nine parameter settings described in Table 5.3. We see that the RTR algorithm can find high-quality solutions to SDTOP problems that can be solved as LOPs. In nine of 10 problems, at least one parameter setting produced a better solution than the solution produced by Charon and Hudry's LOP code. Four of the nine parameter settings produce a higher average profit than Charon and Hudry's solution. The smallest average profit (741426) is only 0.05% less than the largest average profit (744841).

In Table 5.5, we present the results for the nine best parameter settings on the 130 $SPERANZA$ problems from Sets I, II, and III and compare them against VRP-SDTOP. Columns 2 through 10 are the results for the nine RTR variants. Column 11 is the result for the VRP-SDTOP algorithm. Column 12 is the best result produced by any of the 70 parameter sets. We see that parameter sets seven, eight and nine produce the highest three average profits for Set I. For Set II, parameter sets five, seven, and nine produce the highest average profits. For Set III, parameter sets six, eight, and nine produce the highest average profits. Over all 130 problems, parameter set nine produces the largest average profit (12880) followed closely by parameter set eight (12870) and seven (12861). VRP-SDTOP does very poorly on each set of problems. It produces an overall average profit (2097) only 16% as large as parameter set nine. This indicates that minimizing distance alone, without accounting for the pairwise profits, is not a good strategy for solving the SDTOP.

There is very little difference in the results produced by any of the nine RTR

variants in Table 5.5. The smallest average profit (12336) is only 4% less than the largest average profit (12880). When we consider the entire collection of 70 parameter sets that we tried, the smallest average profit (9375) is 28% less than the largest. Of the nine best RTR variants, eight use the All12 local optimization setting. Parameter set nine, which produces the largest average profit, uses the All local optimization setting. The 12Only setting is not used in the best nine variants. Six of nine variants use an intensity setting of 5, and seven use an initial deviation of 0.5. Seven variants use a neighbor list size of 75 and none use 10. Seven of nine use a downhill cut-off value of 4. All but one method uses the Remove-Route-Shakeup procedure. Based on our results, for a fixed runtime, we recommend setting parameters to use the All12 local optimization setting, an intensity setting of 5, an initial deviation of 0.5, a neighbor list size of 75, a downhill cut-off of 4, and the Remove-Route-Shakeup procedure.

In Figure 5.2, we show the result of applying RTR to a 199-node SDTOP. In Figure 5.3, we show the meta-route for the solution in Figure 5.2. In each figure, the thickly drawn edges represent the first edge in the tour. The figures show that SDTOP solutions have little or no resemblance to typical "good" VRP or TOP solutions which tend to include routes that are good TSP tours, individually, and have minimal overlap with other routes. Given the poor performance of VRP-SDTOP on Sets I - III of the $SPERANZA$ problems, this is not a surprise.

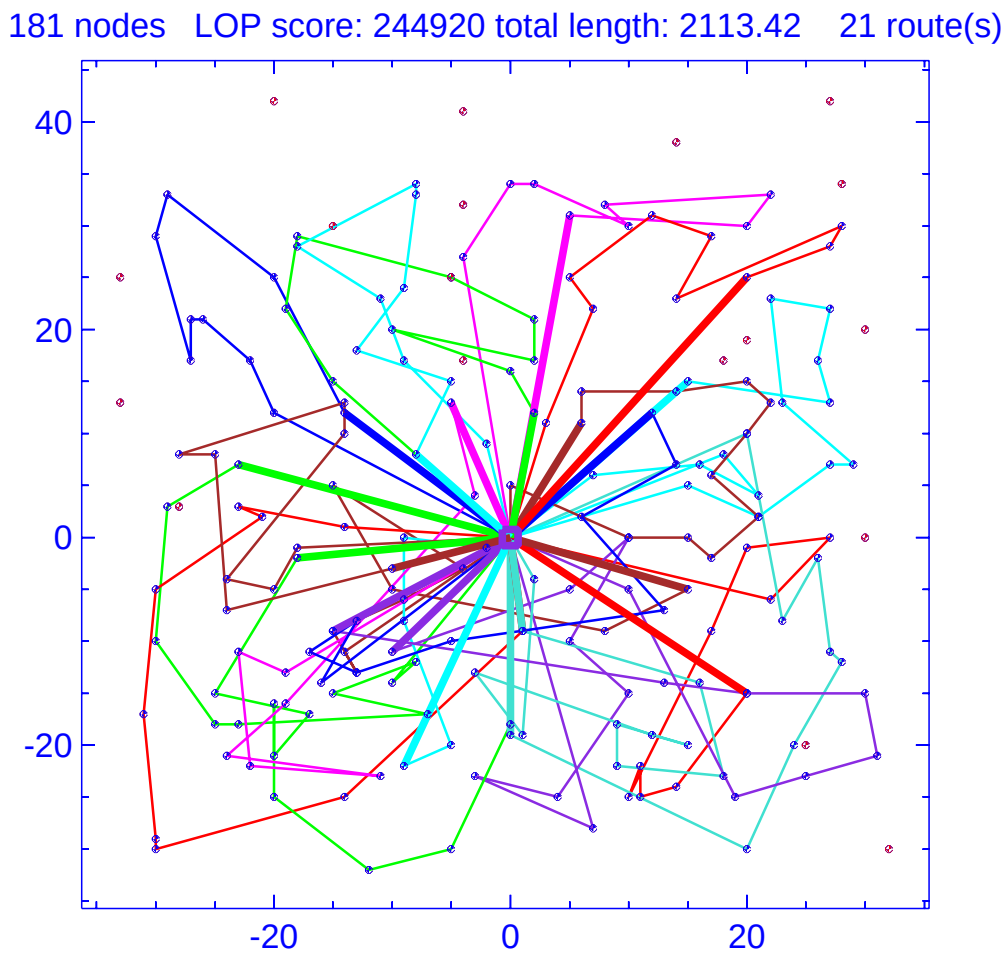

Figure 5.2: Solution to a 199-node SDTOP in which 181 nodes are visited by 20 vehicles (route 21 contains all unvisited nodes).

5.7 Conclusions

In this chapter, we described a new combinatorial optimization problem called the Sequence-Dependent Team Orienteering Problem that combines aspects of orienteering, routing, and ordering problems. We modeled the SDTOP with three different formulations. We developed a record-to-record travel algorithm that solves the SDTOP in reasonable time and showed that it produces solutions that appear

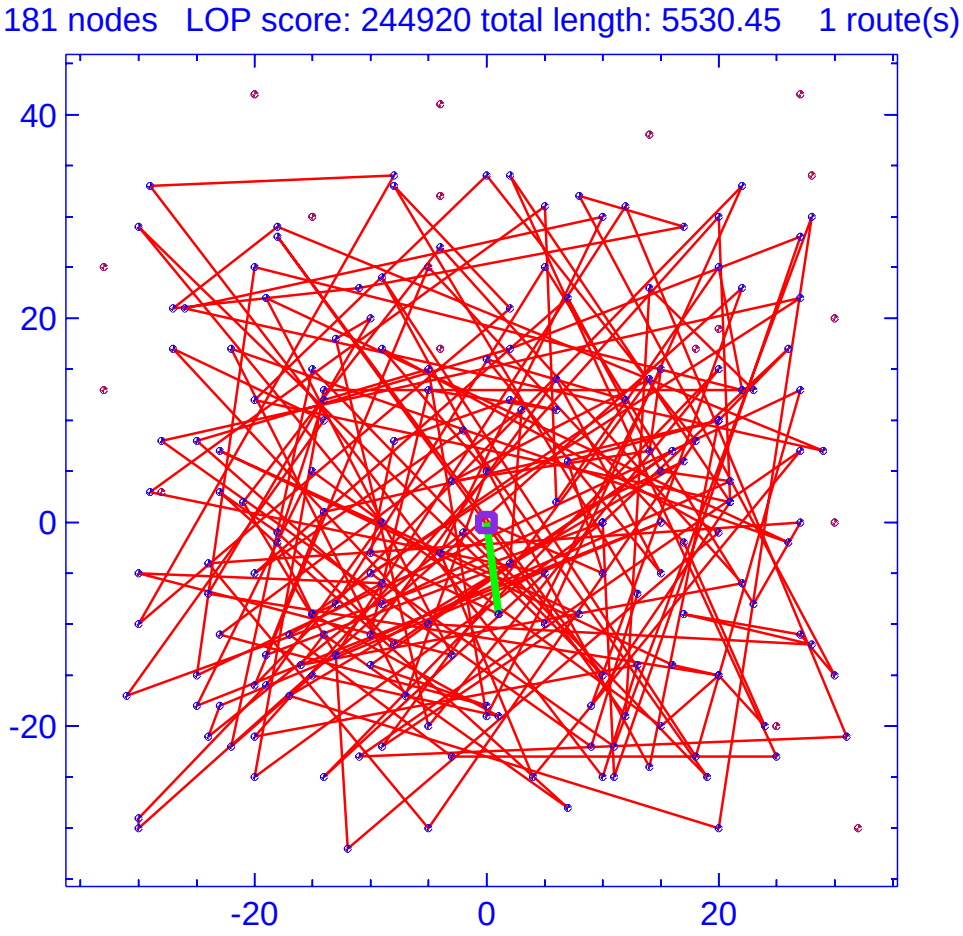

Figure 5.3: Meta-route for the solution in Figure 5.2.

to be of high quality in a reasonable amount of time.

In future work, we will allow each vehicle to leave the depot at any time, $t \geq 0$. Some meta-routes that were previously possible using only infeasible vehicle routes may now be feasible. We will also allow each vehicle to loiter at any target for an arbitrary amount of time. Again, some meta-routes that were previously possible only with infeasible vehicle routes will now be feasible. In both cases, some of the now-feasible meta-routes may produce better solutions than before. Both

modifications add considerable complexity to an already very difficult problem.

Chapter 6

Conclusions

In this dissertation, we studied three combinatorial optimization problems that have real-world applications. We developed a Steiner-zone heuristic and a record-to-record travel heuristic, created 516 benchmark problems, and studied the performance of our algorithms on all benchmark problems. We found that our algorithms are very effective, producing high-quality solutions quickly.

In the first problem, the Close-Enough Traveling Salesman Problem (CETSP), we minimize the distance of a Hamiltonian cycle that passes within a specified distance of each node. The problem has applications in aerial reconnaissance. General versions of this problem have been studied in the literature, but only a few papers have developed algorithms for solving the CETSP. We formulated the CETSP as a mixed-integer, nonlinear program (MINLP) and showed that the lower bounds derived from this formulation are very weak. We developed a three phase Steiner-zone heuristic (SZH) to solve the CETSP in which n nodes are reduced to m intersections of disks called Steiner-zones (Phase I), a tour sequence is assigned to the Steiner zones using any available TSP solver (Phase II), and the distance of the tour is minimized by moving the location of the points that visit the Steiner zones (Phase III). We developed an exact procedure and a heuristic procedure to solve Phase III. We generated a set of 48 benchmark problems with up to 1001 nodes using the 2D

Euclidean norm where the disks in a problem have the same radius. We conducted computational experiments to compare two variants of SZH to 13 heuristics. We found that SZH is very fast, needing less than one second to solve a problem on average and no more than four seconds to solve the most difficult problems. On average, SZH is the most accurate of the heuristics across a wide range of problem sizes and structures.

The second problem, the Close-Enough Vehicle Routing Problem (CEVRP), is a multiple-vehicle CETSP in which each node has a demand that must be satisfied. The CEVRP can be applied to unmanned aerial vehicle route planning where efficient routes are valuable not only to save fuel but also to maximize the amount of intelligence that can be gathered with the available resources. The CEVRP is new to the operations research literature. We formulated the CEVRP as a MINLP and showed that the lower bounds provide no useful information. We used SZH to solve the CEVRP by ensuring that the total demand for any Steiner zone does not exceed the maximum vehicle capacity in Phase I and by incorporating a state-of-the-art Vehicle Routing Problem (VRP) solver [39] into Phase II. We generated 48 benchmark problems with up to 1001 nodes using the 2D Euclidean norm where the disks in a problem have equal radii. We compared four variants of SZH with four baseline heuristics that we developed. We found that the variant that spent too little time on Phase II (SZVRP1) produced solutions very quickly but without much accuracy. The variant that spent too much time on Phase II (SZVRP4) produced the most accurate solutions but was very slow. The variants that spent a moderate amount of effort solving Phase II (SZVRP2, SZVRP3) produced good solutions fairly quickly.

One of the non-Steiner-zone heuristics was more accurate than any variant of SZH for problems in which there was a large amount of disk overlap (it was the least accurate method overall). Across all problems, we found that the best variant of SZH (SZVRP2) was the third most accurate (having an average deviation from the best solution of 3%) and the third fastest (solving problems in an average of 4.5 seconds) of the eight heuristics.

Chapter 4 was motivated by the results found in Chapters 2 and 3. In those chapters, our computational experiments revealed that although SZH produced better solutions faster than other methods when considering all problems, for specific types of CETSP and CEVRP problems, some methods were consistently more accurate than SZH. For example, for a set of seven CETSP problems in which there is a very small amount of disk overlap, the GTSP2 heuristic (described in Chapter 2) was almost 5% more accurate than any SZH variants (although GTSP2 took several hundred thousand seconds, on average, to solve a problem). We studied the structure of the CETSP results found by GTSP2 and used our findings to develop three new Steiner-zone heuristics, the minimum-angle heuristic (MAH), Phase IV post-processor, and MAH + Phase IV. We applied the new heuristics to the 48 benchmark problems from Chapter 2 and the 48 benchmark problems from Chapter 3 and found that the accuracy of SZH was improved substantially with only a reasonable increase in computation time.

We extended the Steiner-zone heuristic to solve several variants of the CETSP and the CEVRP. For instance, the disks surrounding each node in real-world CETSP and CEVRP applications are unlikely to have the same radius. Problems in three

dimensions could have practical application in undersea exploration and surveillance. It is possible that a vehicle may only be able to move forwards and backwards and side-to-side for which the Manhattan norm is more appropriate than the Euclidean norm. We extended SZH to solve CETSPs and CEVRPs for problems using the 2D Manhattan, 3D Euclidean, and 3D Manhattan norms. We generalized SZH to allow the radius of each disk or sphere to differ. For all variants, we compared the performance of SZH with several heuristics on benchmark problems that we generated.

SZH takes advantage of geometrical properties of disks and spheres to produce high-quality solutions to the CETSP and CEVRP quickly. SZH includes one Phase I heuristic for 2D, two unique Phase I heuristics for 3D, one heuristic for solving Phase III, and two heuristics for Phase IV. SZH uses three TSP solvers, one VRP solver, or one genetic algorithm to solve Phase II and uses optimization software to solve integer programs, second-order cone programs, and general nonlinear programs in Phase III. Our computational experiments on 208 benchmark CETSP and 208 benchmark CEVRP problems demonstrate that the Steiner-zone concept, as applied in SZH, works very well across a wide range of problem sizes and types. SZH can be extended to interesting variants of the CETSP and CEVRP such as letting each disk's radius be a function of time. It can also be applied to more general forms of the CETSP and CEVRP, such as the TSP with Neighborhoods (TSPN) and VRP with Neighborhoods (VRPN) where disks are replaced by general convex regions.

The third problem, the Sequence-Dependent Team Orienteering Problem (SD-TOP), is a multi-vehicle orienteering problem in which the profit received for visiting

any node is dependent on the entire sequence of nodes visited. This problem is new in the operations research literature. It is applicable in problems of aerial reconnaissance in which not all targets (nodes) may be visited given the limited resources available and the value of the intelligence gathered at a particular target is dependent upon where the target is located in the overall sequence of visited targets. Unlike similar problems in the literature, which allow sequences of nodes to be fixed, we let the objective function determine the best overall sequence. We formulated the SDTOP as a mixed-integer program (MIP) in three different ways. Each formulation answers the following question in a different manner, "What happens if multiple vehicles arrive at targets simultaneously?" and includes a large number of side-constraints. For example, we can specify a minimum and maximum number of the available vehicles that must be used in any solution. The formulations are too complex to solve to optimality for all but the smallest problems (about five nodes and three vehicles). We developed a record-to-record travel heuristic to solve the SDTOP and modified 130 Team Orienteering Problems with up to 200 nodes to create benchmark SDTOP problems. We generated 10 additional benchmark problems that can be solved as a Linear Ordering Problem (LOP), an optimization problem for which high-quality solvers exist. Our heuristic found solutions better than those found by the LOP solver for nine of the 10 problems. We tried 70 different sets of parameters for our algorithm on the 130 problems to determine the best settings for our heuristic and compared the results against a baseline method. We found that our heuristic produced high-quality results in a reasonable computation time.

This dissertation is designed to promote the further study of the CETSP,

CEVRP, and SDTOP. The author will provide an executable version of his software with a GUI interface along with data and results in file format to interested readers and can be reached at **wmennell@hotmail.com**.

Appendices

Appendix A

The Steiner-Zone Heuristic (SZH) and the Manhattan Norm

In Chapter 2, we applied the Steiner-zone heuristic (SZH) to 21 CETSP problems in 2D using the Euclidean norm. In Chapter 3, we applied the Steiner-zone heuristic to 48 CEVRP problems in 2D using the Euclidean norm. In this appendix, we apply the same heuristics to the 48 CETSP problems and 48 CEVRP problems using the Manhattan norm.

The CETSP and CEVRP formulations given in Chapters 2 and 3 can be modified to use the Manhattan norm. We replace the square root term in the objective function and the constraint requiring all edges to have non-zero length with $|x_i - x_j| + |y_i - y_j|$. We note that the constraint requiring the representative point for node i to lie within $disk(i)$ is not modified.

Due to the excessive computation time of the genetic algorithm used by the GTSP methods, we reused the tour sequences found with the Euclidean norm and applied Phase III using the Manhattan norm. For all Steiner zone methods, we used the Manhattan norm in Phase I to calculate the distance between disks (using the Euclidean norm in Phase I sometimes produced better results but solution quality was generally poorer). The CETSP methods (TILE1 - TILE4, MERGE, HULL) made available to us from Dong et al. [27] and Gulczyinski et al. [43] were implemented only for the Euclidean norm and are not included in this appendix. In each table in this appendix, columns are ordered from best to worst (left to right) by

overall average deviation or CPU time.

A.1 CETSP Results

In Table A-1, we give the results on the 21 $TSPLIB$ problems and the 27 $GEOMETRIC$ problems using equal radius and the 2D Manhattan norm. We note that although GTSP2 and GTSP1 reuse the tours found with the Euclidean norm, the GTSP genetic algorithm, as integrated into HYBRID1 and HYBRID2, is able to use the Manhattan norm in its computations.

We see that GTSP2 produces the shortest tours for four low overlap ratio $TSPLIB$ problems and five medium overlap ratio $TSPLIB$ problems. HYBRID2 produces the shortest tours for four of the remaining low and medium overlap ratio problems. LK-SOCP produces the shortest tours for five high overlap ratio problems. The two Steiner zone methods find shorter tours than both LK-SOCP and YUAN+ in 31 of 48 problems. These results are similar to the Euclidean norm results except that GTSP2 is no longer the most accurate method for the low overlap ratio problems. This may be due in part to not solving a GTSPs using the Manhattan norm.

In Table A-2, we give the percentage deviation from the best solution for each problem. On average, the two methods based on the generalized TSP and the exact Phase III (HYBRID2, GTSP2) produce the smallest deviations (0.74%, 1.14%) for problems with a low overlap ratio. After the four methods that use the generalized TSP, the two methods based on Steiner zones (SZ2, SZ1) are next best with averages of 4.33% and 4.42%, respectively.

For $TSPLIB$ problems with a medium overlap ratio, GTSP2 produces the smallest average (3.60%). Both Steiner zone methods and both hybrid methods are next best with an average deviation of about 8.50%.

For problems with a high overlap ratio, the two methods based on Steiner zones (SZ1, SZ2) and the two hybrid methods (HYBRID1, HYBRID2) produce the smallest average deviations (1.99%, 1.95%, 2.80%, and 1.76%, respectively). The two methods based on the generalized TSP (GTSP2, GTSP1) produce the largest deviations (43.98% and 112.68%, respectively).

Over all 48 problems, HYBRID2 and HYBRID1 are the most accurate methods, with an average deviation of 2.43% and 3.56%, respectively. SZ2 and SZ1 are next best with average deviations of 4.57% and 4.74%, respectively.

In Table A-3, we give the computation times for the six heuristics on the 48 problems. As in the Euclidean case, the two methods based on the generalized TSP (GTSP2, GTSP1) are computationally expensive and the hybrid methods are expensive for low and medium overlap problems while the remaining five methods take seconds to solve problems. Over all 48 problems, LK-SOCP and the two methods based on Steiner zones (SZ1, SZ2) are the fastest, with average times of 0.560, 0.590, and 1.818 seconds, respectively.

A.2 CEVRP Results

The results for the 48 CEVRP test problems with equal radius and 2D Manhattan norm are given in Table A-4. We see that, for the low overlap ratio $TSPLIB$ problems, SZVRP4 produces four best solutions. For the medium overlap ratio $TSPLIB$ problems, CW-SOCP produces five best solutions, and for the high overlap ratio $TSPLIB$ problems, CW-SOCP produces seven best solutions.

CW-SOCP performs well on the $Team$ problems, finding three best solutions. The remaining $GEOMETRIC$ problems are dominated by SZVRP4 and SZVRP3. Each method finds eight best solutions for the remaining 20 problems. Taken together, SZVRP4 and SZVRP3 find 14 best solutions for the $ConcentricCircles$, $Bubbles$, and $RotatingCircles$ problems and $ChaoSingleDep$.

In Table A-5, we computed the percentage deviation from the best solution for the results given in Table A-4. For the low overlap ratio $TSPLIB$ problems, SZVRP3 and SZVRP4 have an average deviation of less than 0.2%. SZVRP2 and GTSP have an average deviation of less than 2%. For the medium overlap ratio $TSPLIB$ problems, CW-SOCP has the smallest average (1.06%) with the remaining seven methods having an average deviation between 2.5% and 6.5%. CW-SOCP dominates the other heuristics for the high overlap ratio $TSPLIB$ problems averaging 0.00%. Only two other methods (SZVRP3, SZVRP4) have an average deviation less than 10%.

Over all 21 $TSPLIB$ problems, CW-SOCP produces the smallest average deviation (2.85%), followed by SZVRP3 (4.19%) and SZVRP4 (4.45%). CW-SOCP

does not perform well on problems with a low overlap ratio but is clearly the best method for problems with medium and high overlap ratios. The Steiner-zone methods perform well across all three overlap ratios.

CW-SOCP performs well on the seven *Team* problems. CW-SOCP has the smallest average deviation (3.32%) with SZVRP2, SZVRP3, and SZVRP4 trailing by almost 2%. CW-SOCP produces very large average deviations on the *ConcentricCircles*, *Bubbles*, and *RotatingDiamonds* problems (16.84%, 19.61%, and 6.77%). SZVRP4 averages under 1% deviation for each group, and SZVRP3 is close behind. Over all *GEOMETRIC* problems, SZVRP4 is the most accurate (1.62%). SZVRP3 and SZVRP2 are both fairly close (2.08% and 3.06%) while CW-SOCP trails all other methods with an average deviation of 12.15%.

Over all 48 problems, we see that SZVRP4 (2.86%) and SZVRP3 (3.01%) are the most accurate methods with SZVRP2 not far behind. CW-SOCP performs well on high overlap ratio problems but has the second largest overall deviation (8.08%).

In Table A-6, we give the computation times for the eight methods. Over all *TSPLIB* problems, CW-SOCP is very fast with an average time of approximately one and one quarter seconds. In addition to CW-SOCP, three methods (SZVRP1, SZVRP2, and Giant TSP) have averages less than six seconds. GTSP is very slow. For the *GEOMETRIC* problems, CW-SOCP averages less than one second and four methods (including SZVRP1 and SZVRP2) average less than five seconds. Over all 48 problems, CW-SOCP is the fastest (1.097 seconds) and GTSP is the slowest (602857 seconds). SZVRP2 and Giant TSP are fast with an average of less than four seconds.

The results are very similar to what we found in Chapter 3 using the Euclidean norm. The results support the observation that the SZH methods (SZVRP1, SZVRP2, SZVRP3, SZVRP4) produce high-quality tours across a wide spectrum of problem types and sizes in reasonable time. The results suggest that CW-SOCP is the best method for non-geometric problems with medium and high overlap ratios. It is the fastest method across all problem types.

If we consider the column representations in Tables A-5 and A-6 to be rankings, SZVRP1, SZVRP2, and SZVRP4 have the best average rank of 3.5. CW-SOCP's average rank is 4 while SZVRP3 and CTD have an average rank of 4.5. CW-SOCP and SZVRP4 perform slightly better with the Manhattan norm than with the Euclidean norm while SZVRP3 does slightly worse. SZVRP2 ranks number one for both norms and SZVRP1 ranks second for the Euclidean norm and first for the Manhattan norm. The combination of speed and accuracy across all problems with either norm makes SZVRP2 a highly competitive method.

A.3 Phase IV with the Manhattan Norm

When using the Manhattan norm, the turn angle of each edge is either 0°or 90°. In order to apply Phase IV, we need meaningful turn angle values for each edge in the tour. Therefore, we calculate the turn angles as if the Euclidean norm were being used.

Table A-4: Tour lengths for eight heuristics on 48 problems with equal radius and 2D Manhattan norm

A.3.1 CETSP

In Tables A-7, A-8, and A-9, we present the results with the Manhattan norm. A 10° range is used for the MAH heuristics ([60°, 69°]). Our experiments showed that [60°, 69°] produced slightly better tours on average than the 10° range we used for the Euclidean norm ([50°, 59°]). For either norm, any 10°interval in the [30°, 69°] produced more accurate solutions than SZH without the minimum angle heuristic.

The tour-length results for the 11 heuristics on the 48 test problems are given in Table A-7. The average deviations from the best solutions in Table A-7 are given in Table A-8. Columns in both tables are ordered by the overall average deviation from best (left) to worst (right).

Over all 48 problems, $SZ3_{0-359}$ finds 40 best solutions. SZ3 finds solutions as good as or better than GTSP2 47 times and finds solutions as good as or better than LK-SOCP 34 times. $SZ2_{0-360}$ equals or is better than GTSP2 48 times and LK-SOCP 32 times. GTSP2 finds the best solution for the five *concentrCircles* problems.

In Table A-8, we give the average deviations from the best solution for the 11 heuristics. $SZ3_{0-359}$ has an average deviation of 0.30% and 0.00% for low and medium overlap ratio $TSPLIB$ problems, respectively, while SZ3 averages 2.28% and 3.43%, respectively. For the high overlap ratio $TSPLIB$ problems, $SZ3_{0-359}$, $SZ3_{60-69}$, and SZ3 have an average deviation of 0.00%. Over all 48 problems, $SZ3_{0-359}$ has an average deviation of 0.30% deviation, and three methods average less than 2% ($SZ3_{60-69}$, SZ3, $SZ2_{0-359}$).

In Table A-9, we give the computation times for the 11 heuristics on the 48 problems. Columns are ordered from fastest (left) to slowest (right). $\mathrm{SZ1}_{60-69}$ and $\mathrm{SZ2}_{60-69}$ are faster than $SZ3$. $\mathrm{SZ1}_{0-360}$ is faster than $\mathrm{SZ2}_{0-360}$.

If we consider the column representations in Tables A-8 and A-9 to be rankings, SZ3 and $\mathrm{SZ3}_{60-69}$ have the best average rank (4.5). The combination of speed and accuracy across all problems with either norm make these two methods highly competitive procedures for the CETSP.

The results for the 48 problems using the Manhattan norm do not provide any new insights on the Steiner-zone heuristic's performance. Instead, they reinforce the observations made in Chapter 4. The MAH, Phase IV, and Phase IV + MAH variants of SZH are more accurate than the standard Steiner-zone heuristic described in Chapters 2 and 3. Phase IV does not increase the computation time unreasonably. If MAH and Phase IV + MAH are applied with 10° ranges, they do not increase computation time unreasonably.

Table A-7: Tour lengths for 11 heuristics on 48 problems with equal radius and 2D Manhattan norm

	$SZ3_{0-360}$	$SZ3_{60-69}$	SZ3	$SZ2_{0-360}$	$SZ1_{0-360}$	$SZ2_{60-69}$	$SZ1_{60-69}$	SZ2	SZ1	GTSP2	LK-SOCP

A.3.2 CEVRP

In Tables A-10, A-11, and A-12, we present the results for 15 heuristics using the Manhattan norm. In order for all the columns in each tables to appear on one page, we refer to the SZVRPk heuristic as SZVk.

The tour lengths for the 15 heuristics on the 48 test problems are given in Table A-10. The average deviations from the best solutions in Table A-10 are given in Table A-11. Columns in both tables are ordered by the overall average deviation from best (left) to worst (right).

Over all 48 problems, SZV3$_{t\ 50-59}$ produces 27 best solutions, SZV4$_t$ produces eight best solutions, and SZV3$_t$ produces eight best solutions.

In Table A-11, we give the average deviations from the best solution for the 15 heuristics. SZV3$_{t\ 50-59}$ has an average deviation of 0.54% over all 48 problems while the SZV1 variants have an average deviation over 6.40%. As with the Euclidean norm, for each of the four pairs of Phase IV methods (SZVk_t and SZVk_v, for $k = 1, \ldots, 4$), the TSP-based Phase IV method produces better average deviations than the associated VRP-based Phase IV method.

In Table A-12, we give the computation times for the 15 heuristics on the 48 problems. Columns are ordered from fastest (left) to slowest (right). As with the Euclidean norm, the SZV1 variants are fastest (SZV1 averages under six seconds per problem), and the VRP-based Phase IV methods (SZVk_v) are faster than the associated, more accurate TSP-based Phase IV methods (SZVk_t).

If we consider the column representations in Tables A-11 and A-12 to be

rankings, $SZV3_v$ has the best average rank (5.5) with $SZV3_t$ close behind (6). $SZV2_v$ is third with an average rank of 7. $SZV3_v$ deviates from the best solution an average of only 2.03% and solves each problem in an average of 82.094 seconds. $SZV2_v$ deviates an average of 5.40% from the best solution but solves each problem in 13.253 seconds. $SZV2_v$ and $SZV3_v$ combine accuracy and speed to produce high-quality solutions fairly quickly.

Table A-10: Tour lengths for 15 heuristics on 48 CEVRP problems with equal radius and 2D Manhattan norm

	$SZV3_{t\ 50-59}$	$SZV4_t$	$SZV3_t$	$SZV3_v$	$SZV4_v$	$SZV2_{t\ 50-59}$	$SZV4_{50-59}$	$SZV3_{50-59}$	$SZV2_{50-59}$	$SZV2_t$	$SZV2_v$	SZV4	$SZV1_{50-59}$	$SZV1_t$	$SZV1_v$

A.4 Conclusions

In this appendix, we applied the Steiner-zone heuristic to 48 CETSP problems and 48 CEVRP problems with the Manhattan norm. We applied the MAH, Phase IV, and MAH + Phase IV variants of SZH to the 48 CETSP problems and 48 CEVRP problems. We found that several variants produce high-quality results in a very reasonable amount of time. This is the same as what we found in Chapters 2 - 4 for 48 CETSP problems and 48 CEVRP problems with the Euclidean norm.

Appendix B

The Steiner-Zone Heuristic (SZH) in 3D

The CETSP and CEVRP can be applied to problems in three dimensions. Unmanned Aquatic Vehicles (UAVs) are used to provide data collection for scientific and military purposes. For example, torpedo-shaped ocean gliders are being used to improve 3D models of the central California coastal region [17]. Monitoring specific underwater regions may require approaching only within a specified distance of each region. In this appendix, we extend SZH to solve the CETSP and the CEVRP in three dimensions, using either the Euclidean and Manhattan norms.

B.1 Formulation

In the 3D CETSP, a tour must cross a sphere of radius r_i surrounding every node i except the depot (node 0), which has no sphere. Any tour that touches or passes through node i's sphere (hereafter referred to as $sphere_i$) successfully visits node i. Node i is a fixed point in the plane at coordinate (a_i, b_i, c_i). We denote this coordinate as $orig(i)$, the origin of $sphere_i$. Let (x_i, y_i, z_i) be the coordinate on the tour that is close enough to node i. Coordinate (x_i, y_i, z_i) is known as node i's *representative point*. x_i, y_i, and z_i are unbounded continuous variables. Let e_{ij} be a binary variable equal to 1 if node i immediately precedes node j on a tour and 0 otherwise. Let ϵ be the smallest length of any edge.

Using either norm, constraint (2.2) is replaced by (B1). Node i's representative point must lie within the sphere of radius r_i surrounding $orig(i)$. That is, it must lie within $sphere_i$.

$$(x_i - a_i)^2 + (y_i - b_i)^2 + (z_i - c_i)^2 \leq r_i^2 \qquad i = 1, \ldots, n \tag{B1}$$

In 3D Euclidean space, the objective function (2.1) and constraint (2.6) are replaced by (B2) and (B3).

$$\text{Minimize} \quad \sum_{i=1}^{n} \sum_{j=1}^{n} e_{ij} \sqrt{(x_i - x_j)^2 + (y_i - y_j)^2 + (z_i - z_j)^2} \tag{B2}$$

$$\sqrt{(x_i - x_j)^2 + (y_i - y_j)^2 + (z_i - z_j)^2} \geq \epsilon \qquad i, j = 1, \ldots, n \tag{B3}$$

In 3D Manhattan space, the objective function (2.1) and constraint (2.6) are replaced by (B4) and (B5).

$$\text{Minimize} \quad \sum_{i=1}^{n} \sum_{j=1}^{n} e_{ij} (|x_i - x_j| + |y_i - y_j| + |z_i - z_j|) \tag{B4}$$

$$|x_i - x_j| + |y_i - y_j| + |z_i - z_j| \geq \epsilon \qquad i, j = 1, \ldots, n \tag{B5}$$

For the remainder of this appendix we assume that $r_i = r_j$ for all nodes i and j.

B.2 SZH in 3 Dimensions

In two dimensions, a $SZ(k)$ is the non-empty intersection of k disks. $SZ(k)$ is characterized by its base node and the upper and lower angles of intersection

between the origin of the base node and the $k-1$ other disks. We do not need to know any information about the amount of overlap that exists between the k disks or where in the plane the boundaries of the Steiner zone are. The base node and upper and lower angles of intersection suffice to guarantee that a feasible point can be found. All disks lie in the X-Y plane. Phase I of SZH reduces a set of n disks to a set of m Steiner zones. $l_{contain}$ is the length of a side of the smallest square containing all n disks. The overlap ratio of a CETSP is the ratio of r to $l_{contain}$.

In three dimensions, a $SZ(k)$ is the non-empty intersection of k spheres. Since the intersection of convex sets is convex, and spheres are convex, a $SZ(k)$ is a three-dimensional convex region. In 3D, $l_{contain}$ is the length of a side of the smallest cube containing all n disks. An overlap ratio of 0.15 in 3D is likely to have fewer spheres overlapping than the number of disks that would overlap given the same overlap ratio in 2D. The Phase I heuristic was designed for two-dimensional space and must be modified for spheres rather than disks. We developed two possible Phase I heuristics for three-dimensional CETSPs and CEVRPs. The first, called $3D_{AN}$, applies the two-dimensional Phase I algorithm directly in three dimensions and then corrects for any infeasibilities found. The second, called $3D_{NUM}$, numerically approximates the boundary of the spherical polygon formed by the intersection of the base node's sphere and the $k-1$ other spheres.

B.2.1 $3D_{AN}$

$3D_{AN}$ applies the two-dimensional Phase I heuristic directly in three dimensions. We developed it with the goal of achieving similar speeds as in two dimensions. A trade-off exists, however, since $3D_{AN}$ finds infeasible representative points for some Steiner zones or determines that the intersection of k disks is non-empty when in fact it is empty.

Given $sphere_i$ and $sphere_j$ less than $r_i + r_j$ units apart, project $orig(i)$ and $orig(j)$ onto the X-Y plane, the X-Z plane, and the Y-Z plane. For each projection, calculate the two-dimensional angles of intersection for the two disks. A Steiner zone for nodes i and j, denoted SZ_{ij}, found by $3D_{AN}$ is characterized by the three sets of upper and lower angles of intersection and the base node i. In two dimensions (the X-Y plane), a chord connects the points on base node i's perimeter lying at the upper and lower angles of intersection (see Figure 2.12). Any point along this chord is feasible to the Steiner zone. We use the midpoint for simplicity. In three dimensions, we choose the midpoint of the chord for each of the three projections (X-Y, X-Z, Y-Z). This produces three sets of coordinates, (x_1, y_1), (x_2, z_1), and (y_2, z_2). The point chosen to represent SZ_{ij} is the midpoint of each dimension's two points, $(\frac{x_1+x_2}{2}, \frac{y_1+y_2}{2}, \frac{z_1+z_2}{2})$.

For example, let $orig(i) = (150, 2, 26)$, $orig(j) = (155, 9, 13)$, and $r_i = r_j = 9$. In Figure B.1, we show the projection of the spheres onto the X-Y, X-Z, and Y-Z planes. $sphere_i$ and $sphere_j$ intersect but $3D_{AN}$ finds an infeasible point. Calculating the intersection of two spheres based on three two-dimensional projections of

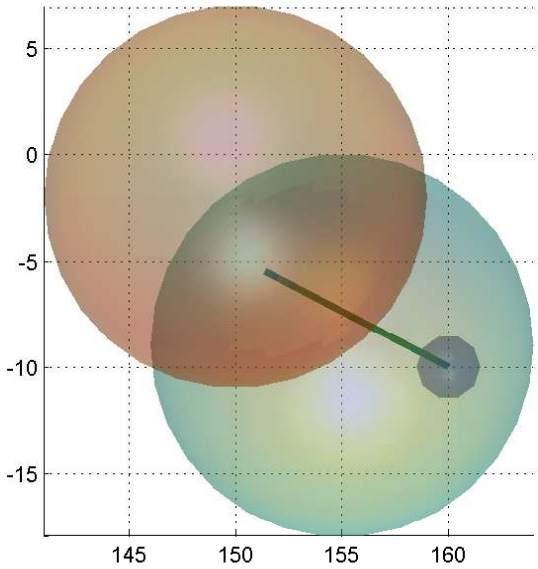
those spheres loses valuable information. $3D_{AN}$ sometimes finds $SZ(k)$'s that do not exist. For other (feasible) $SZ(k)$'s, $3D_{AN}$ may calculate infeasible representative points.

In two dimensions, given two feasible Steiner zones, SZ_{ij} and SZ_{ik}, both based on node i, if the angles of intersection for SZ_{ik} overlap those for SZ_{ij} then SZ_{ijk} must exist (see Figure 4.8). This is not true in three dimensions. That is, given a feasible Steiner zone SZ_{ij} based on node i, if Steiner zone SZ_{ik} exists and the angles of intersection for SZ_{ik} overlap those for SZ_{ij} in all three projections, then SZ_{ijk} does not necessarily exist. However, in order to compute Steiner zones proportionately as fast as SZH does in two dimensions, $3D_{AN}$ assumes that SZ_{ijk} exists if the angles of intersection for SZ_{ij} overlap the angles of intersection for SZ_{ik} in all three projections, even if this is not always the case.

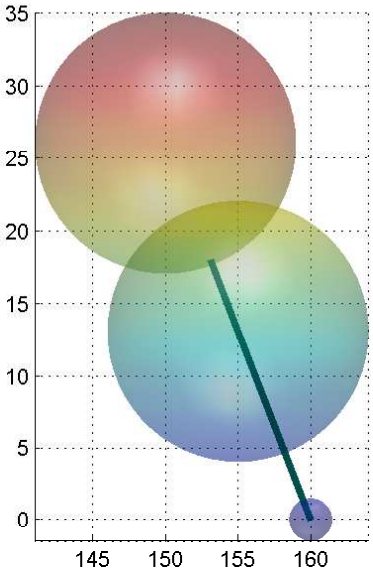
Due to the possible errors it introduces, when $3D_{AN}$ is complete, we check all Steiner zones for feasibility. Any member node, i, in a $SZ(k)$ for which $SZ(k)$'s representative point is infeasible is removed. Node i becomes a $SZ(1)$.

B.2.2 $3D_{NUM}$

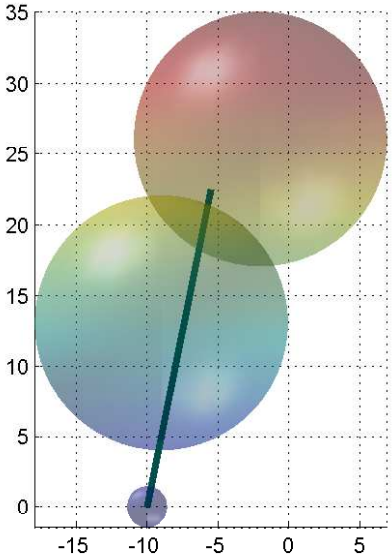
The two-dimensional Phase I algorithm is fast because it efficiently answers the question: do the $SZ(k)$ and the $SZ(2)$ being considered (both with base node i) have a non-empty intersection? If the answer is yes, then the angles at which the $k+1$ disks intersect relative to $orig(i)$ are returned. Nothing beyond the $orig(i)$ and the two angles of intersection are required.



(a) X-Y Projection



(b) X-Z Projection



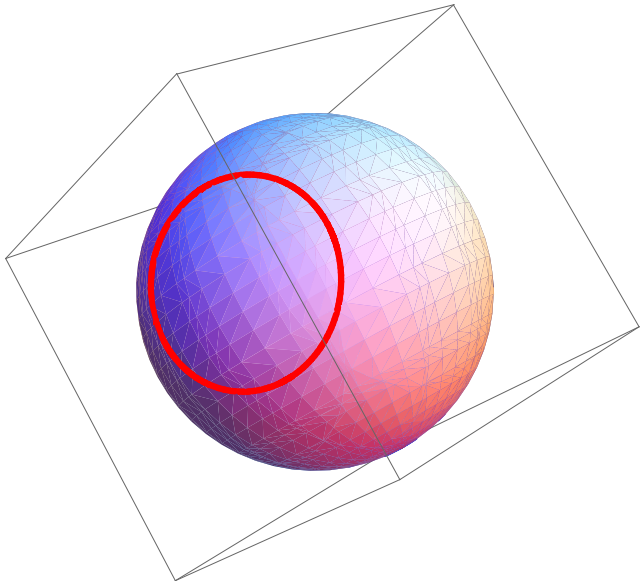
(c) Y-Z Projection

Figure B.1: The two large spheres form a $SZ(2)$ (the small sphere is the depot). $3D_{AN}$ chooses an infeasible representative point.

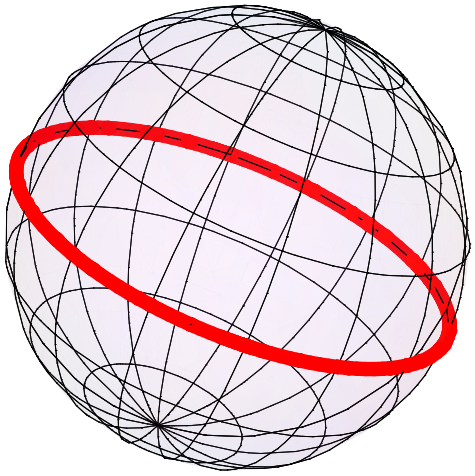
$3D_{AN}$ tries to answer this question in three dimensions using an analog of the two-dimensional method but has serious flaws. In the computational chemistry literature, much has been written about how to determine if k spheres intersect [57, 71]. However, these methods consider all k spheres simultaneously, whereas SZH does not. Finding a $SZ(k)$ in a graph of n nodes where n is large (say 100) using methods from computational chemistry would involve checking $\binom{n}{k}$ different possibilities. This is computationally inefficient.

Before describing $3D_{NUM}$, we define several geometric concepts. A *spheric section* [69] is the curve formed by the intersection of a plane and a sphere. The plane at which any sphere intersects $sphere_i$ forms a spheric section on the boundary of $sphere_i$. If the spheric section has a radius less than r_i, then it is called a *small circle* [20]. Otherwise, it is called a *great circle*. We show examples of both in Figure B.2. Given $orig(i)$ and $orig(j)$ (i is the base node) within $r_i + r_j$ units of each other, we can calculate a point-wise approximation of the spheric section that is formed. If $sphere_j$ intersects $sphere_i$ at exactly one point, then the spheric section describing their intersection is a single point on the boundary of $sphere_i$.

Given k spheres, if $k-1$ spheric sections overlap on the surface of sphere k, then the k spheres must have a non-empty intersection (a $SZ(k)$ exists for these k spheres). If the $k-1$ spheric sections do not overlap on sphere k's surface, then the k spheres either may or may not overlap. That is, for a $SZ(k)$ to exist in three dimensions, it is sufficient but not necessary for $k-1$ spheric sections to intersect on the surface of sphere k. We illustrate this in Figure B.3. In Figure B.3(a), the two (hidden) spheres ($sphere_j$ and $sphere_k$) whose intersection with $sphere_i$



(a) A small circle



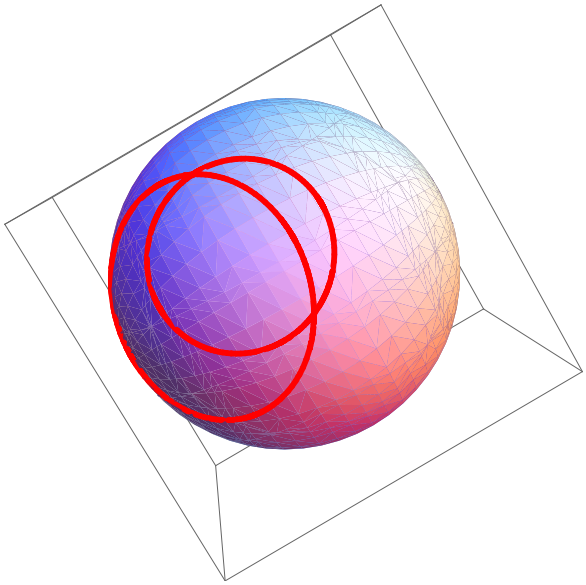
(b) A great circle

Figure B.2: Two spheric sections

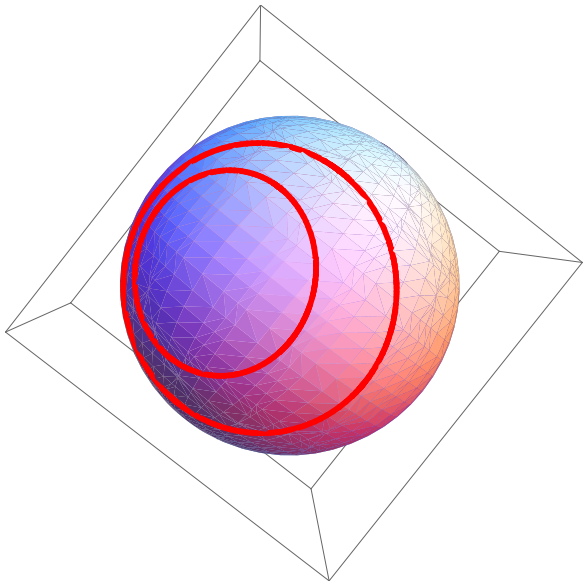
produces the small circles on $sphere_i$'s surface must also intersect each other. The same is true in Figure B.3(b), but the small circles do not overlap on $sphere_i$'s surface because $sphere_j$ and $sphere_k$ are almost collinear. A Phase I method that determines Steiner zones solely by the intersection of small circles on the surface of $sphere_i$ cannot recognize that any point in $sphere_j$'s (smaller) spheric section must be feasible for $sphere_k$. $3D_{NUM}$ is such a method.

The intersection of multiple spheres with base node i's sphere creates spherical polygons on the surface of $sphere_i$. A *spherical polygon* [70] is a closed geometric figure on the surface of a sphere formed by the arcs of great circles. An example is shown in Figure B.4. We also use *spherical polygon* to denote the closed geometric figure on the surface of a sphere formed by the arcs of both great and small circles. When more than two spheric sections intersect on the boundary of $sphere_i$, the result is called a *spherical polygon*. Any point in a spherical polygon, sp, is within r_i units of each node i whose sphere partially determines sp.

Using $3D_{NUM}$, a $SZ(k)$ with base node i is characterized by a numerical approximation of the perimeter of the spherical polygon on $sphere_i$'s surface formed by the intersection of $sphere_i$ and the other $k-1$ spheres. Given a $SZ(k)$ and a $SZ(2)$, both based on node i, if their spherical polygons intersect, then we have found a $SZ(k+1)$ based on node i. We create the numerical approximation of $SZ(k+1)$'s spherical polygon by piecing together the feasible portions of the $SZ(k)$'s and the $SZ(2)$'s spherical polygons. If $k = 1$, the approximation is a spheric section. If $k = 2$, it resembles a spherical lens shape. If $k = 3$, it resembles a spherical triangle. For $k \geq 4$, there is no term to describe the shape. Any point from the approximation



(a) Two intersecting small circles imply that a $SZ(3)$ exists



(b) One small circle contains the other - the spheres that produce non-intersecting small circles may or may not intersect, but in this case they do.

Figure B.3: A $SZ(3)$ exists in both figures.

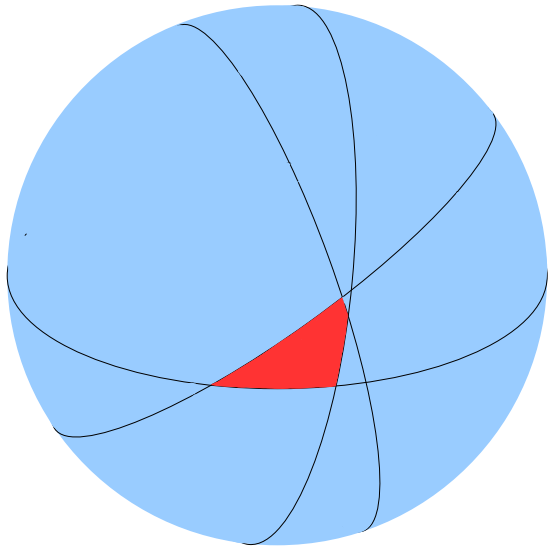


Figure B.4: A four-sided spherical polygon (the four great circles are produced by four (hidden) spheres intersecting the visible sphere).

of the polygon may be chosen to represent $SZ(k)$. As a result, all Steiner zones found by $3D_{NUM}$ are feasible and have feasible representative points.

In summary, $3D_{AN}$ should be initially faster than $3D_{NUM}$ at reducing a graph of n spheres into m Steiner zones because it uses 2D analytical methods rather than numerical methods. The 2D analytical methods do not guarantee feasible 3D Steiner zones; however, fixing the infeasibilities is easy. For problems where a large number of Steiner zones found by $3D_{AN}$ are infeasible, the number of Steiner zones after removing the infeasible member nodes and making singletons, m, is close to n, the number of nodes in the graph. The size of the TSPs solved in Phase II and the size of the QCPs solved in Phase III are not much smaller than if Phase I were not applied at all. Problems may take longer to solve than if we applied $3D_{NUM}$ to begin with, thereby guaranteeing feasible Steiner zones. One benefit of having m close to n is that the Steiner zones will have low degree. Feasible solutions will not

be forced to make inefficient visits to Steiner zones of high degree (and very small area) which may be in out-of-the-way locations.

B.3 Phase IV in 3D

The Phase IV post-processor (see Chapter 4) tries to minimize the total angle cost for a tour. In three dimensions, we can either calculate turn angle using the projection of the tour onto the XY axis, or we can factor in the change in elevation (the z-axis) for each edge into the definition of turn angle. Our default setting runs Phase IV for both methods.

B.4 Visualization

Visualizing a three-dimensional CETSP or CEVRP is non-trivial. We have developed three methods coded in MATLAB® [3], one fast, one slow, and one very slow. Each method is integrated into our C++ CETSP/CEVRP code. The first method, *BubblePlot*, uses code written by Bodin [14] to draw each sphere rather than Steiner zones. Figures B.5 and B.6 show the solution tour for a 101-node CETSP plotted amongst all 100 spheres (plut the depot). The spheres are drawn with 10% and 20% opacity, respectively. *BubblePlot* quickly produces a picture of how a tour visits all n spheres, especially when the overlap ratio is low. When the overlap ratio is medium to high, the overlapping spheres obscure the figure too much to obtain any useful information visually.

The second method, *NUMER*, calculates a NUMERICAL approximation of

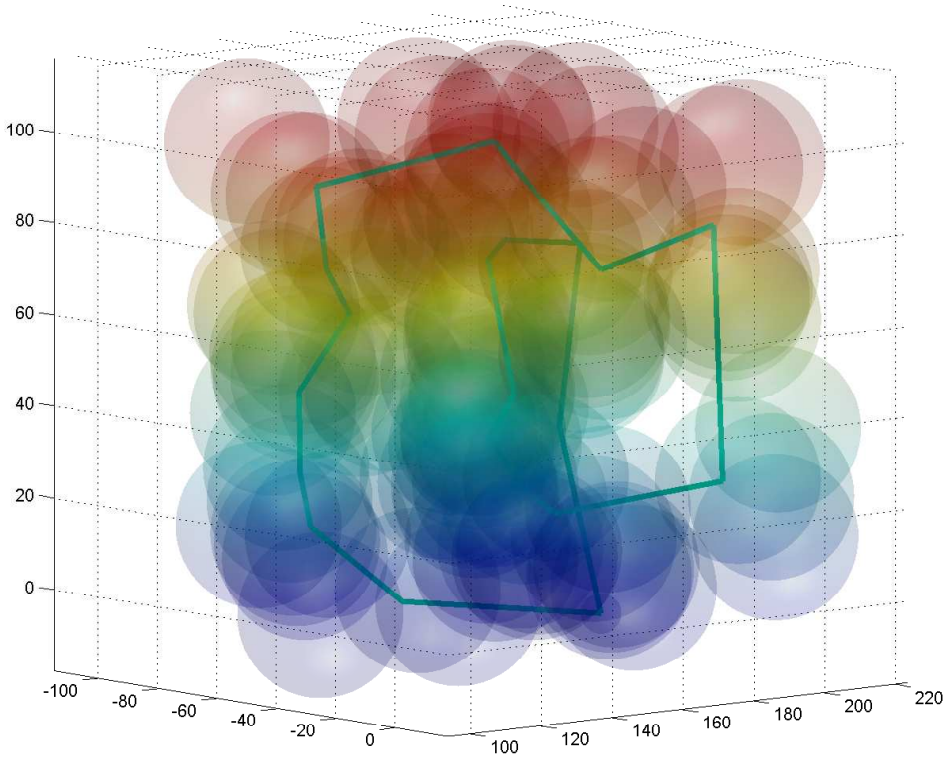

Figure B.5: All spheres are shown at 10% opacity.

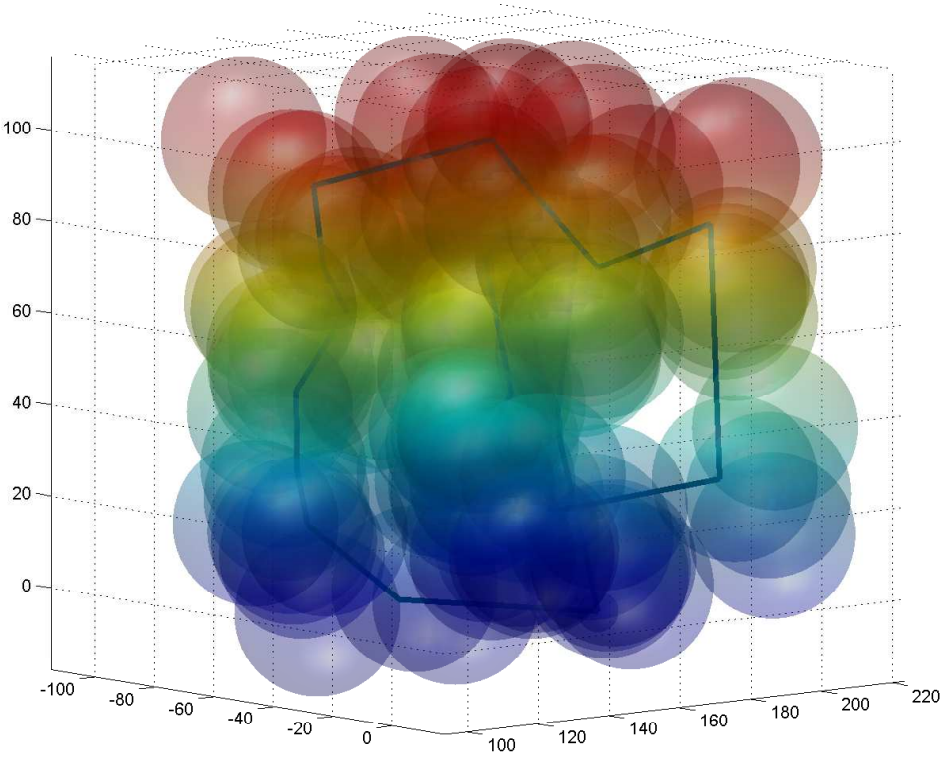

Figure B.6: All spheres are shown at 20% opacity.

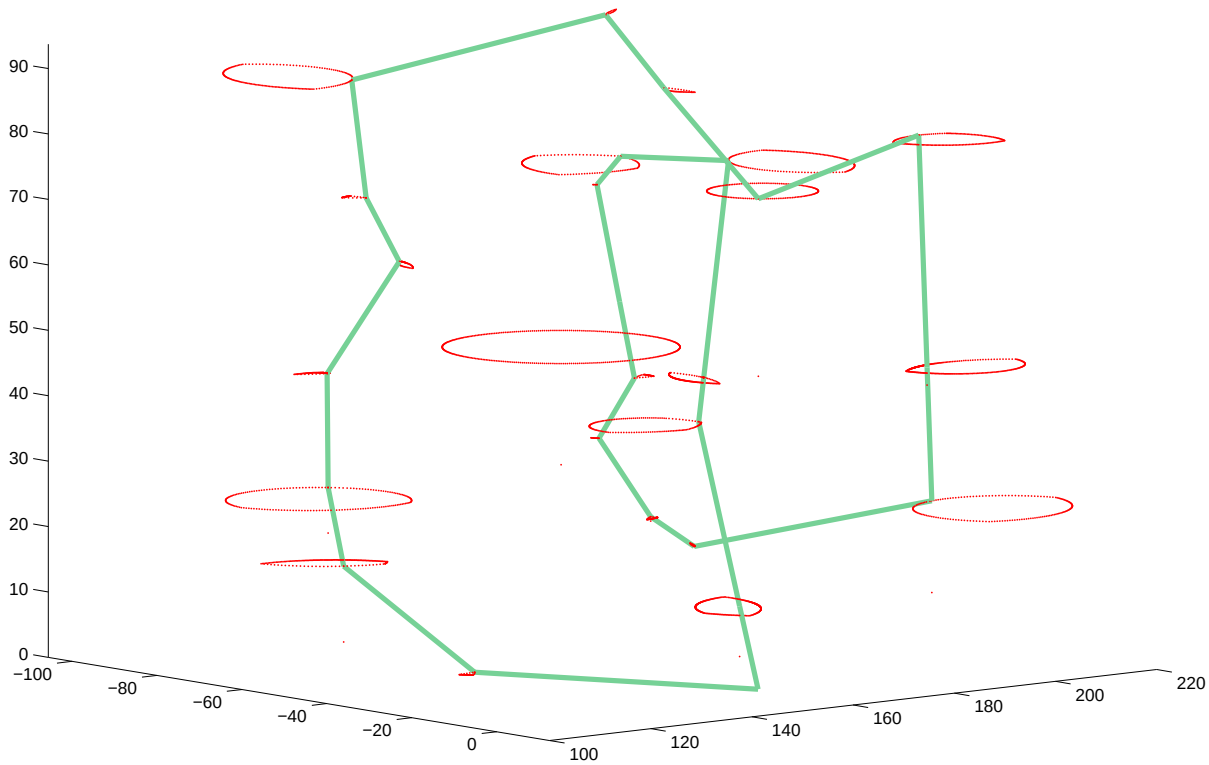

Figure B.7: 2D representation of the Steiner zones drawn in 3D.

the convex hull of each Steiner zone. For each Steiner zone, we calculate 360 point approximations for each of α meridians, where the meridians for SZ_i are connected to SZ_i's representative point. Figures B.7 through B.12 depict the same 101-node CETSP and solution as in Figures B.5 and B.6, plotted for different values of α. When $\alpha = 1$, the two-dimensional convex hulls are calculated but displayed in three dimensions. We show this in Figure B.7. As α increases, $NUMER$ becomes slower but produces more detailed images of each Steiner zone. When $\alpha = 180$, the convex hulls are highly detailed; the file conversion process altered the images to appear completely solid here.

The third method, $POLY$, calculates a polygonal approximation of each Steiner zone's convex hull. $POLY$ is based on code written by D'Errico [26] that tests the

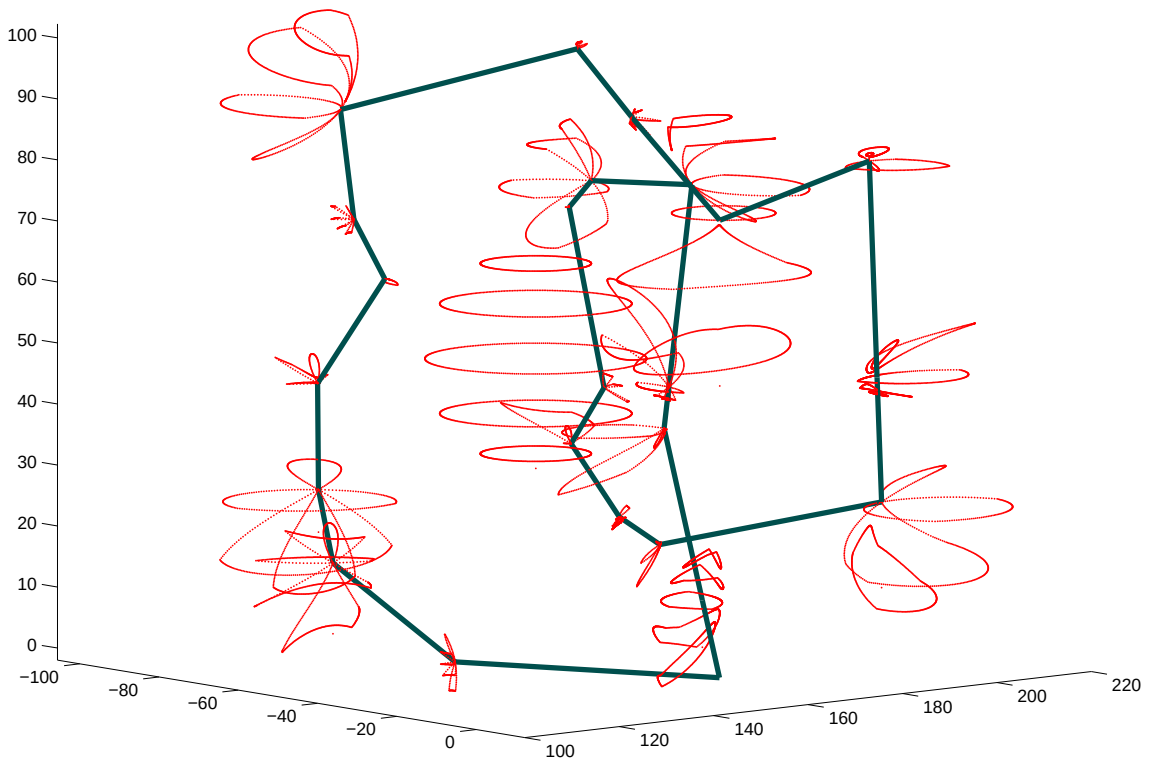

Figure B.8: Six longitudinal lines represent each SZ.

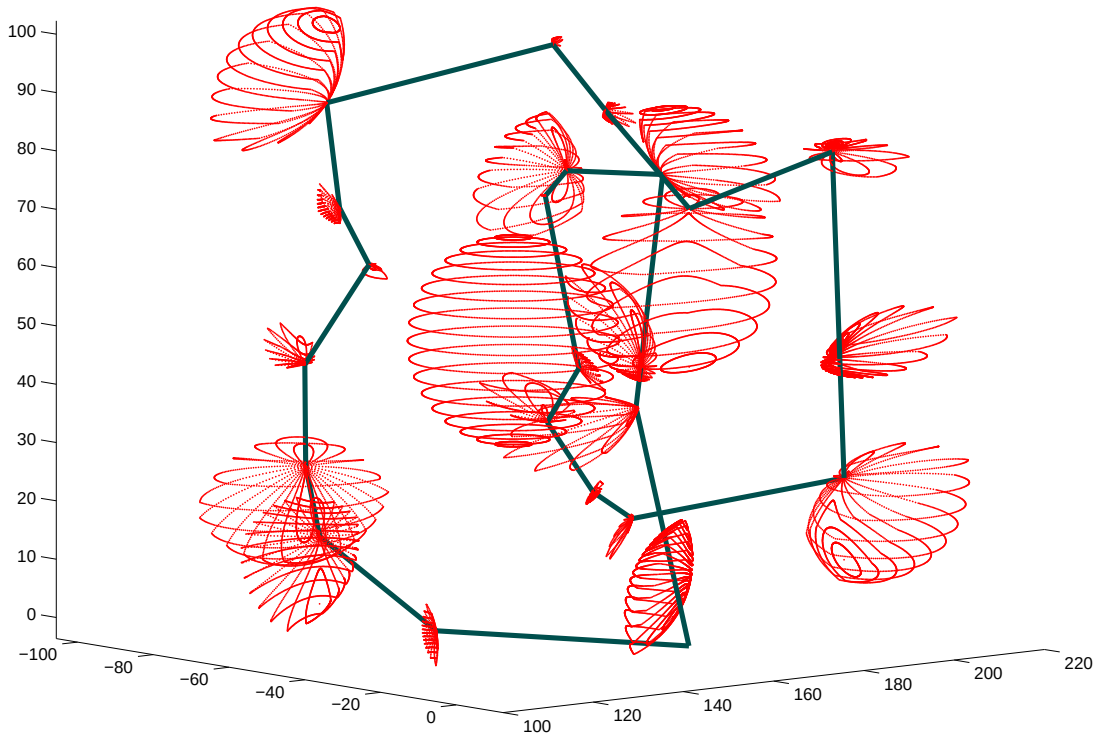

Figure B.9: 18 longitudinal lines represent each SZ.

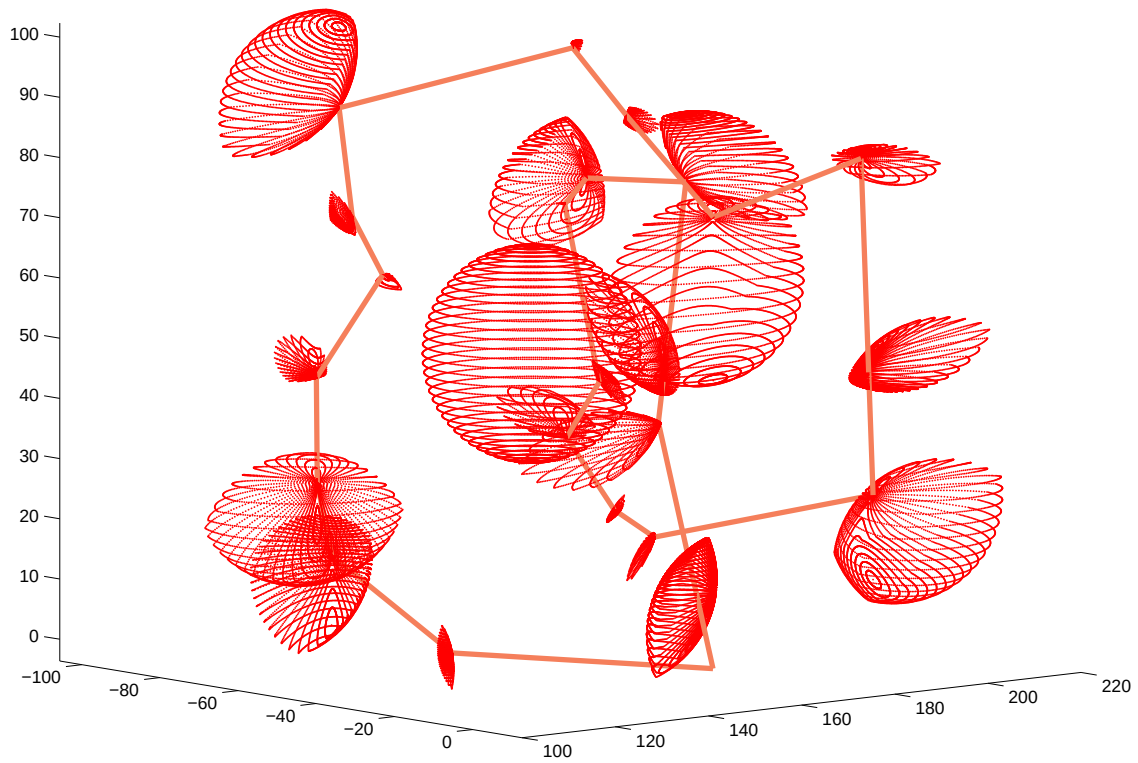

Figure B.10: 36 longitudinal lines represent each SZ.

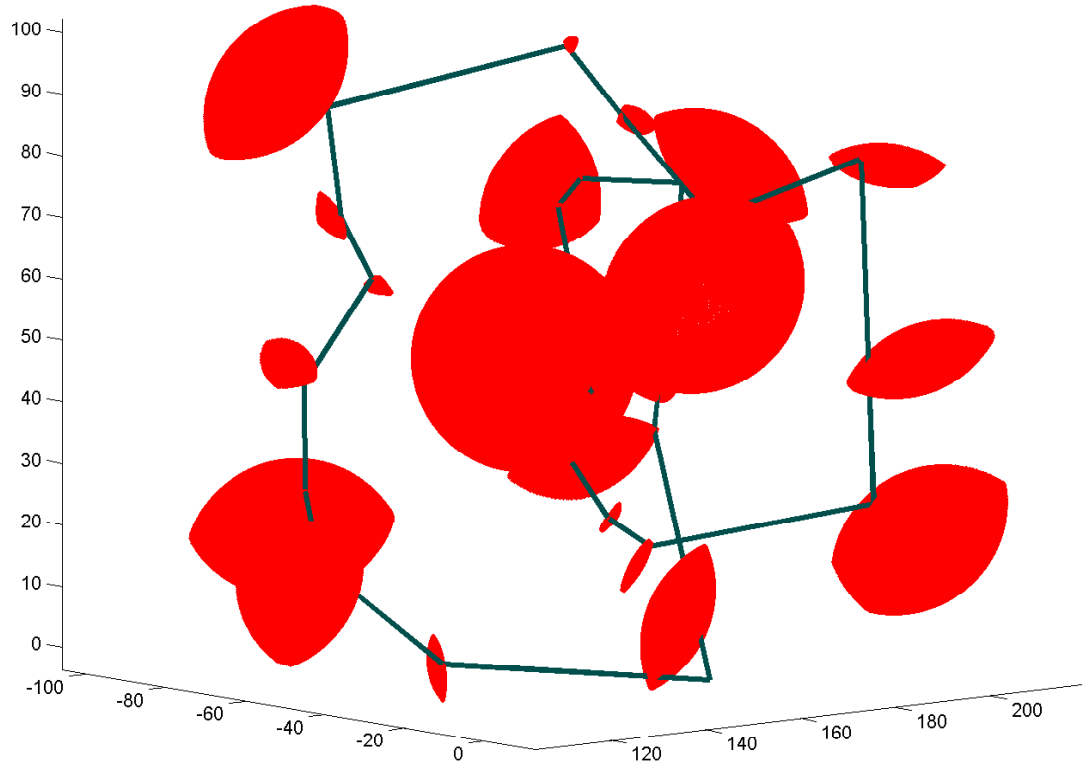

Figure B.11: 60 longitudinal lines represent each SZ.

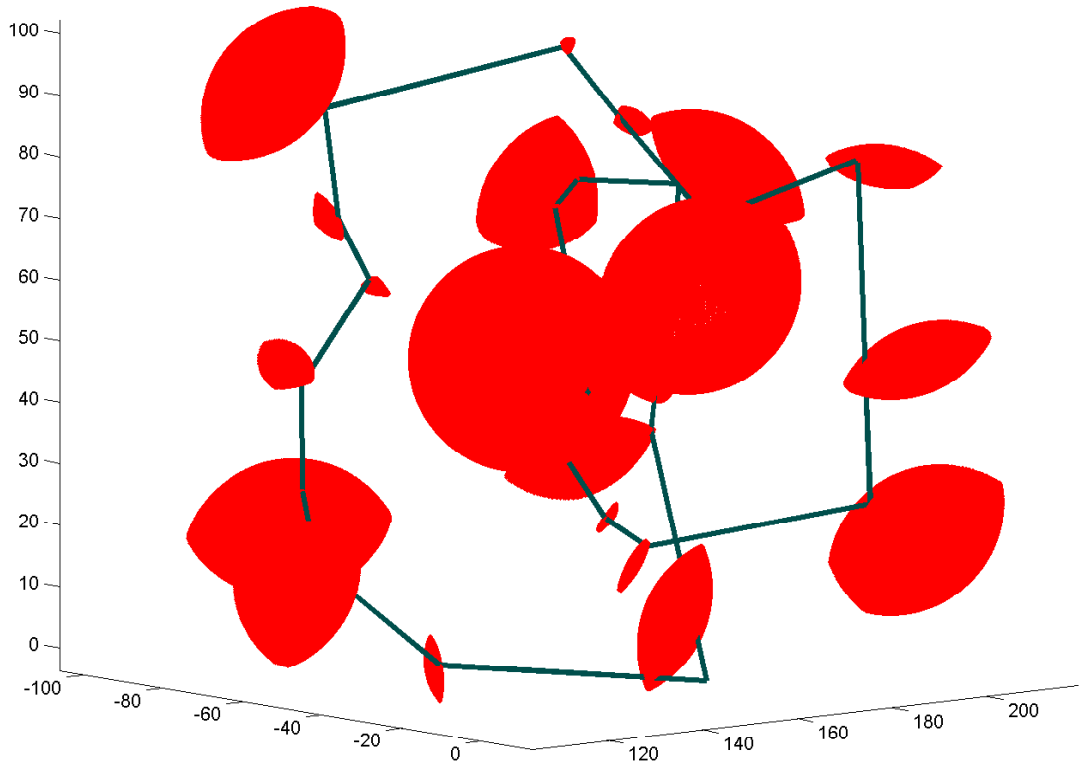

Figure B.12: 180 longitudinal lines represent each SZ.

members of an arbitrary set for inclusion in the convex hull of another set. For a given $SZ(k)$ with base node i, $POLY$ first computes the intersection of node i's sphere with one of the other $k-1$ spheres, where each sphere is approximated polygonally. Let the set of points in both spheres be called S_2. S_2 is intersected with one of the $k-2$ spheres to form the set S_3. This is repeated until the set S_k remains, containing the points that lie in all k spheres. The level of visual detail for $POLY$ depends on the number of points, β, used to approximate each sphere. As with $NUMER$, there is a tradeoff between speed and level of detail. For a small β (between three and five), $POLY$ is fast, but the spherical approximations are too coarse to be of much value. For β much larger than 20, $POLY$ is extremely slow. Due to its polygonal nature, $POLY$ does not approximate each Steiner zone

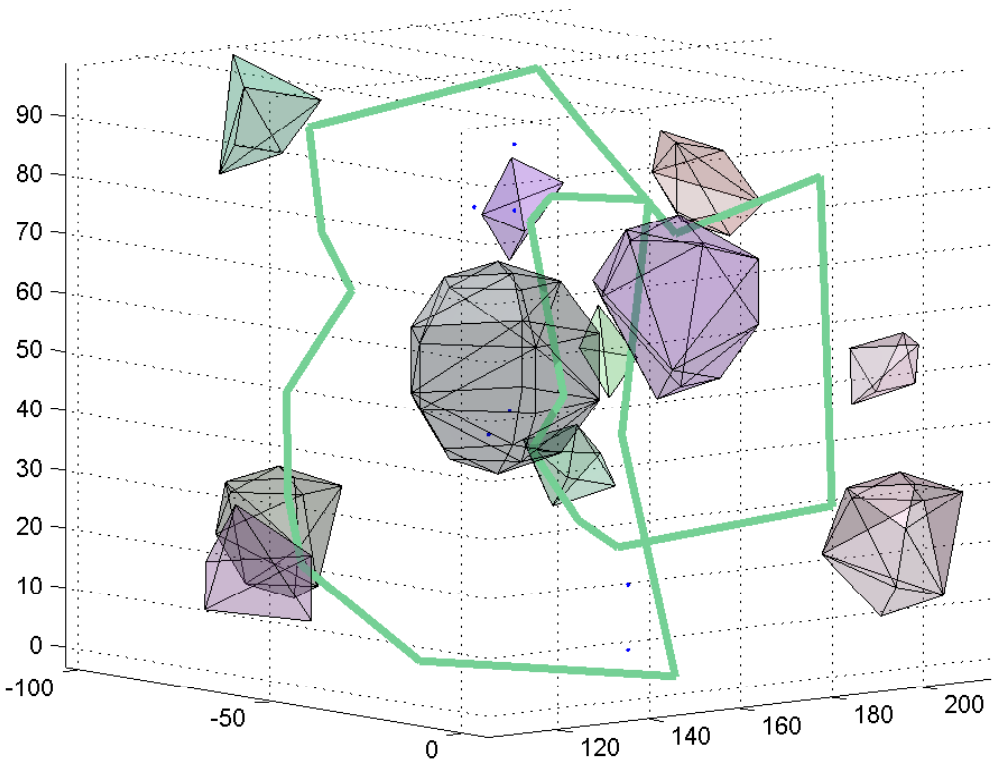

Figure B.13: $\alpha = 5$

as accurately as $NUMER$, even for a large β. Figures B.13 through B.16 depict the same 100-node CETSP and solution as Figures B.5 through B.12 for different values of β. Figure B.17 shows a closeup of two polygonally approximated Steiner zones for $\beta = 50$. Even for large values of β, as in Figure B.16, the tour sometimes appears not to touch some of the Steiner zones. The tour is feasible, but the polygonal approximation of the Steiner zones makes it appear that the solution is infeasible.

B.5 CETSP Results

We created 3D benchmark problems for the CETSP by adding z-dimensional coordinates to the 21 $TSPLIB$ and seven $Team$ problems described in Chapter 2.

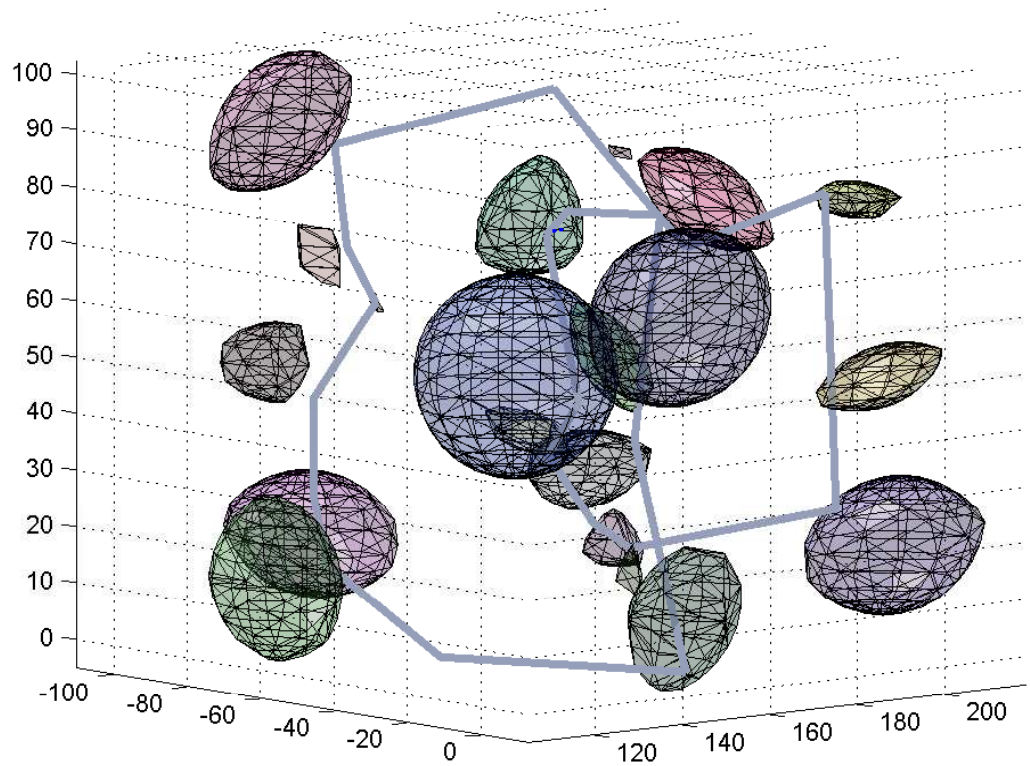

Figure B.14: $\alpha = 15$

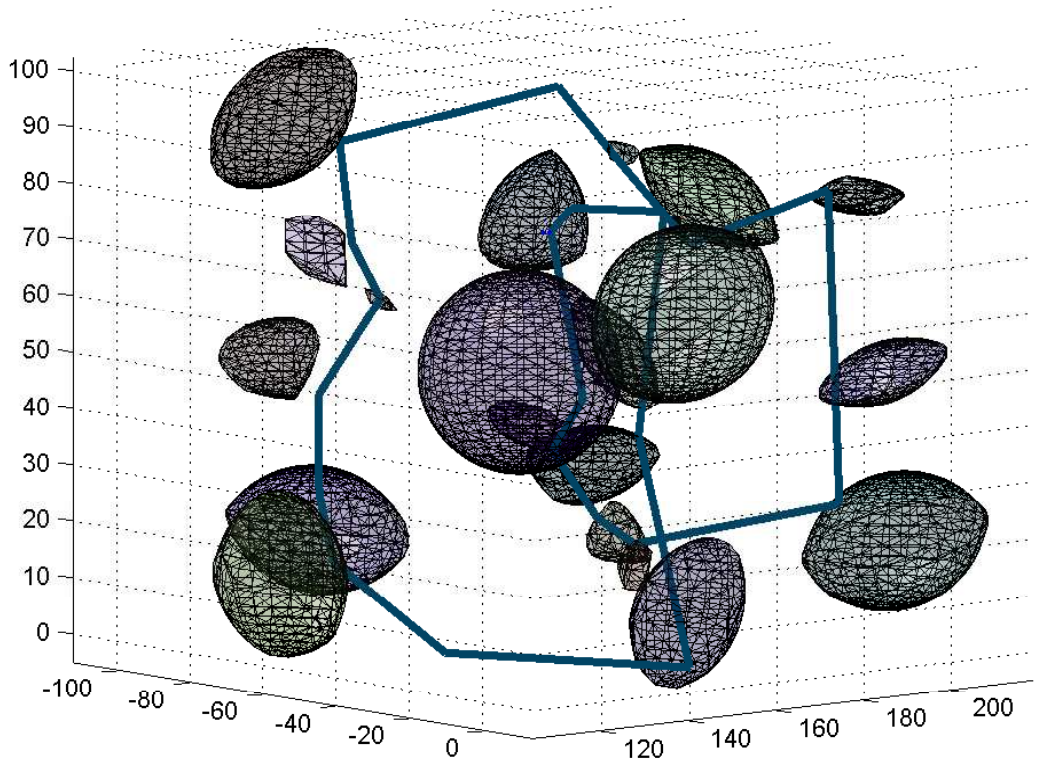

Figure B.15: $\alpha = 30$

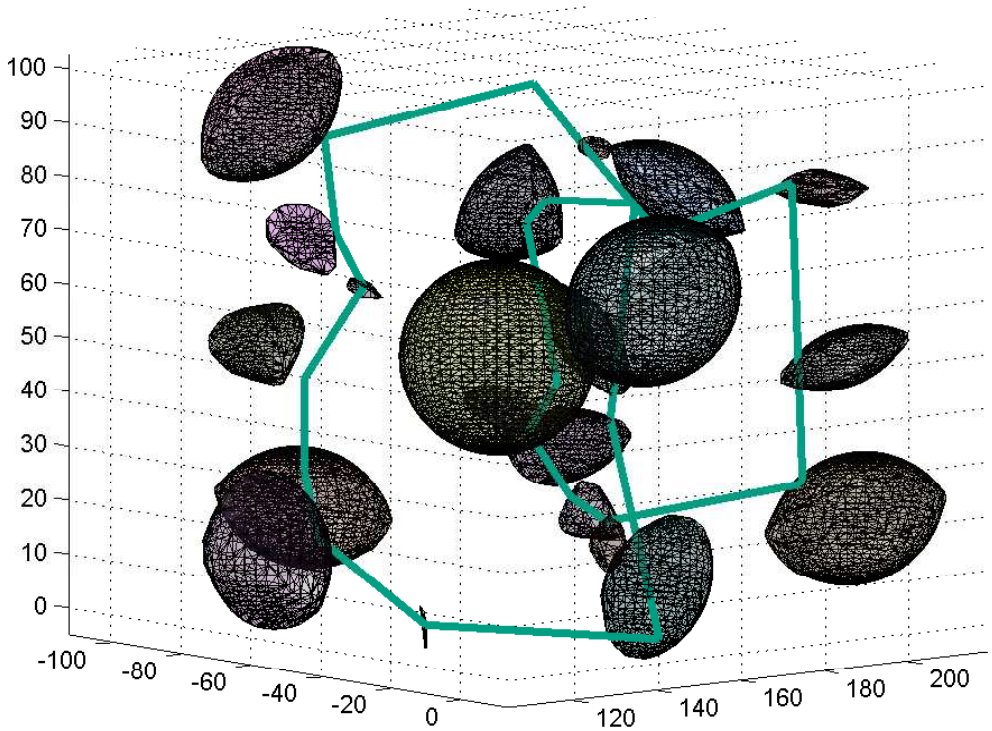

Figure B.16: $\alpha = 50$

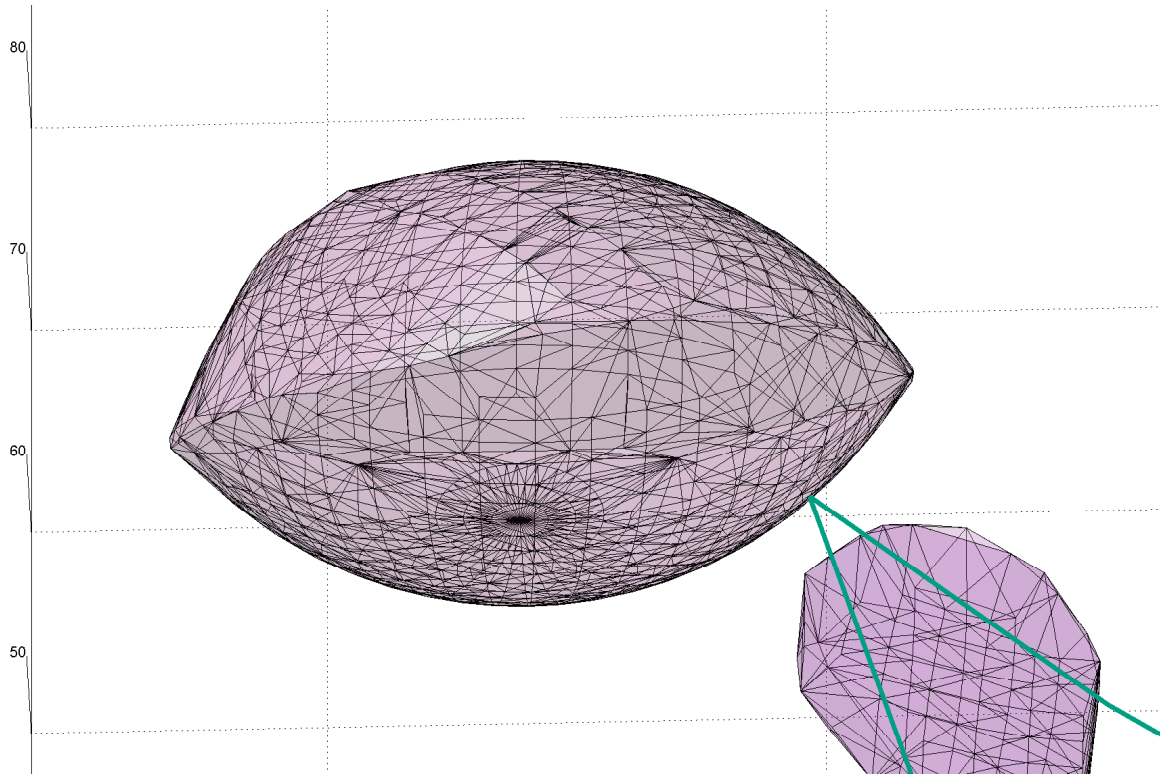

Figure B.17: A close-up of two Steiner zones when $\alpha = 50$

The remaining 20 $GEOMETRIC$ problems that were created specifically in two dimensions are not solved as 3D problems. All problems have almost the exact same overlap ratio in 3D as in 2D. Instead of thinking of 0.02, 0.1, and 0.3 as low, medium, and high overlap ratios (as we did in 2D), we treat them as very low, low, and medium-high overlap ratios in 3D.

We coded six CETSP solution methods for comparison purposes. SZ3$_{an}$ and SZ3$_{nu}$ are the same as the SZ3 method described in Chapter 4 except that SZ3$_{an}$ implements the $3D_{AN}$ Phase I solver and SZ3$_{nu}$ implements the $3D_{NUM}$ Phase I solver. SZ2$_{an}$ and SZ2$_{nu}$ are the same as the SZ2 method described in Chapter 2 except that SZ2$_{an}$ implements the $3D_{AN}$ Phase I solver and SZ2$_{nu}$ implements the $3D_{NUM}$ Phase I solver. YUAN+ and LK-SOCP are the same methods described in Chapter 2 except that they solve Phases II and III in 3D. We could not implement SZ1, CTD, HYBRID1, HYBRID2, GTSP1, and GTSP2 in 3D (SZ1 applies the Ip$_{PhIII}$ Phase III heuristic which does not easily extend to three dimensions. Creating a 3D spherical trapezoidal decomposition algorithm from the 2D circular trapezoidal decomposition heuristic used by CTD would take too long to implement. HYBRID1, HYBRID2, GTSP1, and GTSP2 rely on the code developed for only two-dimensional problems by Silberholz and Golden [67]). DAMON1, DAMON2, DAMON3, DAMON4, HULL, and MERGE were not provided to us with 3D implementations.

In Tables B-1, B-2, and B-3, we present the results for the 28 problems with fixed radius and 3D Euclidean norm. The columns in Table B-1 and B-2 are ordered from left (best average deviation) to right (worst average deviation). The columns

in Table B-3 are ordered left to right from fastest overall to slowest.

In Table B-1, we see that SZ3$_{nu}$ produces 23 best solutions and SZ3$_{an}$ produces eight best solutions (including problems where both methods find the same solution). Without the Phase IV post-processor, $3D_{NUM}$ (implemented by SZ2$_{nu}$) produces better solutions than $3D_{AN}$ (implemented by SZ2$_{an}$) slightly less than half of the time (12 out of 28 times). YUAN+ and LK-SOCP produce only one best solution (on a problem where three out of four Steiner-zone methods also produce the best solution).

In Table B-2, we give the average deviation from the best solutions in Table B-1. SZ3$_{nu}$ is the most accurate of the six methods, with an average deviation of 0.06%. SZ3$_{an}$ is very accurate for the low overlap ratio $TSPLIB$ problems but does poorly (an average deviation greater than 5%) on six of the remaining 20 problems. SZH methods that do not apply the post-processor (SZ2$_{an}$, SZ2$_{nu}$) are between 5% and 7% more accurate than either YUAN+ or LK-SOCP over all 28 problems.

In Table B-3, we compare computation times for the six heuristics. LK-SOCP is the fastest method with an average time of 1.025 seconds. SZ2$_{an}$ and SZ2$_{nu}$ are both fast, averaging between seven and 11 seconds. YUAN+ and both methods applying the Phase IV processor (SZ3$_{an}$, SZ3$_{nu}$) are slow, needing 29.587, 94.595, and 119.947 seconds, respectively.

Over all 28 problems we observe the following: (1) $3D_{NUM}$ is more accurate (approximately 2%) than $3D_{AN}$ for Euclidean 3D equal radius problems. 3D$_{NUM}$ is about 1.3 times slower than 3D$_{AN}$. (2) Methods that use Steiner zones (SZ3$_{an}$, SZ3$_{nu}$, SZ2$_{an}$, SZ2$_{nu}$) are more accurate than those that do not (YUAN+, LK-

SOCP). (3) If we consider the order in which the columns appear in Tables B-2 and B-3, then $SZ2_{an}$ and $SZ2_{nu}$ have the best average rank (3). $SZ3_{an}$, $SZ3_{nu}$, and LK-SOCP follow with an average rank of 3.5. $SZ2_{nu}$ averages 10.335 seconds per problem with an average of 4.28% deviation. It seems to be the most competitive of the six methods.

In Tables B-4, B-5, and B-6, we present the results for the 28 problems with fixed radius and 3D Manhattan norm. $SZ3_{anEuc}$ and $SZ3_{nuEuc}$ are the same as

$SZ3_{an}$ and $SZ3_{nu}$ except that they compute distances when creating the ordered list in Phase I using the Euclidean norm. $SZ2_{an}$, $SZ2_{nu}$, $SZ3_{an}$, and $SZ3_{nu}$ compute the same distances using the Manhattan norm. For all methods, distances in Phase II and Phase III are calculated using the Manhattan norm.

In Table B-4, we see that $SZ3_{nuEuc}$ finds best solutions to 18 of 28 problems. $SZ3_{nu}$ finds the best solution 10 times. The two $3D_{NUM}$ methods that apply the post-processor ($SZ3_{nuEuc}$, $SZ3_{nu}$) produce better solutions than two $3D_{AN}$ methods that apply the post-processor ($SZ3_{anEuc}$, $SZ3_{an}$) 20 of 28 times. $SZ2_{nu}$ produces better solutions than $SZ2_{an}$ only 9 of 28 times.

Table B-5: Percentage deviation from the best solution for 28 problems with equal radius and 3D Manhattan norm

In Table B-5, we show the average deviations from the best solutions in Table B-4 for the 28 problems. $SZ3_{nuEuc}$ and $SZ3_{nu}$ have an average deviation close to 1% over all problems, while $SZ3_{an}$ and $SZ3_{anEuc}$ are close to 8%. $SZ2_{nu}$ is slightly more accurate than $SZ2_{an}$ (8.44% compared to 8.88%). Except for the low overlap ratio $TSPLIB$ problems and three of the high overlap ratio $TSPLIB$ problems ($kroD100, rat195, lin318$), YUAN+ and LK-SOCP produce large average deviations (about 15%).

In Table B-6, we see the average computation times for the eight heuristics over the 28 problems. LK-SOCP is the fastest method with an average of 1.360 CPU seconds. SZH methods that do not apply the Phase IV post-processor ($SZ2_{an}$, $SZ2_{nu}$) are fast with an average of 13 to 17 seconds. The $3D_{NUM}$ methods that apply Phase IV ($SZ3_{nu}$, $SZ3_{nuEuc}$) are slow with an average over 200 seconds.

Over all 28 problems we make the following observations. When applied with Phase IV, $3D_{NUM}$ produces better solutions than $3D_{AN}$. When Phase IV is not applied, $3D_{AN}$ finds more best solutions than $3D_{NUM}$ but has a slightly larger average deviation (8.88% compared to 8.44%). This is because $3D_{NUM}$ does not produce infeasible Steiner zones in Phase I (as described earlier), and therefore has more Steiner zones with degree greater than 1 than $3D_{AN}$ produces. After Phase I, the set of Steiner zones created by $3D_{AN}$ may have a large proportion of singletons (due to the infeasibilities in the Steiner zones that $3D_{AN}$ found). The Phase IV post-processor does not greatly improve a solution tour that already consists of mostly singletons (recall from Chapter 4 that the post-processor iteratively removes Steiner zones, replacing them with duples and singletons). If we consider the column order in Tables B-5 and B-6 to be rankings, then $SZ3_{an}$ and $SZ3_{anEuc}$ have the best average ranking (3.5) of the eight heuristics. The average deviations for these two methods, however, are much poorer than the average deviations for $SZ3_{nuEuc}$, which has an average rank of 4.5.

Over all 28 problems solved using both norms, $SZ2_{nu}$ has the best average rank for the Euclidean norm and the second best average rank for the Manhattan norm. $SZ3_{an}$ has the second best average rank for the Euclidean norm and the best

Table B-6: Computation time for 28 problems with equal radius and 3D Manhattan norm

rank for the Manhattan norm.

B.6 CEVRP Results

We created benchmark problems for the CEVRP in 3D by adding z-dimensional coordinates to the 21 $TSPLIB$ and seven $Team$ problems described in Chapter 3. That is, the CEVRP 3D benchmark problems have the same coordinates as the CETSP 3D benchmark problems in Section B.5 and use the same node demands,

vehicle capacities and maximum tour lengths as the 2D CEVRP problems described in Chapter 3.

We coded 14 CEVRP solution methods for comparison purposes. The 12 SZVRP methods are variants of the SZH. Subscripts t and v indicate methods that use either the TSP-based or VRP-based Phase IV methods described in Chapter 4. Subscripts a and n indicate which 3D Phase I method is used: $3D_{AN}$ or $3D_{NUM}$. For each SZVRPk method described in Chapter 3 (SZVRP1, SZVRP2, SZVRP3, SZVRP4), we implemented 6 different versions: SZVRPk_n, SZVRPk_{vn}, SSZVRPk_{tn}, SZVRPk_a, SZVRPk_{va}, and SZVRPk_{ta}. We do not include any methods subscripted with a in this section. We found that a SZVRPk method subscripted with n consistently produced shorter tours faster than the equivalent SZVRPk method subscripted with a. For example, SZVRP2_{vn} produces a lower average deviation and has a faster average computation time than SZVRP2_{va}.

In 2D, both SZVRP1 and SZVRP2 solved Phase III using the IP_{PhIII} heuristic procedure. Because IP_{PhIII} is not extended to work in three dimensions, all SZVRP methods described here solve Phase III to optimality using the SOCP formulation (see Appendix E).

CW-SOCP solves only Phases II and III of SZH. The Lin-Kernighan TSP heuristic is used to solve Phase II, computing a TSP tour (using a 3D norm) on the n nodes. Phase III is solved to optimality using the SOCP formulation. Giant TSP_{tn} is similar to the Giant TSP method described in Chapter 3 except that Phase I applies the $3D_{NUM}$ heuristic and the TSP-based Phase IV post-processor is applied.

Table B-7: Tour lengths for 28 problems with equal radius and 3D Euclidean norm

In Tables B-7 - B-9, we give our results on the 28 problems with equal radius and 3D Euclidean norm. Columns in Tables B-7 and B-8 are ordered left to right from lowest average deviation to highest. Columns in Tables B-9 are ordered from left to right, fastest average computation time to slowest.

In Table B-7, we present the tour lengths found by the 14 methods. The four variants of SZVRP3 and SZVRP4 that apply the Phase IV post-processor (SZVRP3$_{vn}$, SZVRP3$_{tn}$, SZVRP4$_{vn}$, SZVRP4$_{tn}$) collectively produce 20 out of 28 best solutions. CW-SOCP and Giant TSP$_{tn}$ each find one best solution.

Table B-8 gives the average deviation from the best solutions in Table B-7. For low overlap ratio $TSPLIB$ problems, seven of the 12 SZVRP methods average less than 1% deviation. For medium overlap ratio $TSPLIB$ problems, SZVRP4$_{tn}$ (0.88%) and SZVRP4$_{vn}$ (0.51%) average less than 1% deviation. For high overlap ratio $TSPLIB$ problems, four variants of SZVRP (SZVRP3$_{vn}$, SZVRP3$_{tn}$, SZVRP4$_{vn}$, SZVRP4$_{tn}$) average less than 1% deviation. For SZVRP1 and SZVRP2, the TSP-based Phase IV variants produces better tours on average than the VRP-based Phase IV variants.

Over all 28 problems, SZVRP4$_{tn}$ produces the lowest average deviation (0.59%). Nine SZVRP methods average less than 4% deviation. Giant TSP$_{tn}$ averages over 7% deviation across all problems. CW-SOCP, which does not use Steiner zones, performs poorly on the medium and high overlap ratio $TSPLIB$ problems and the $Team$ problems. CW-SOCP has the highest average deviation across the 28 problems (8.86%).

Table B-8: Percentage deviation from the best solution for 28 problems with equal radius and 3D Euclidean norm

	SZVRP4$_{tn}$	SZVRP4$_{vn}$	SZVRP3$_{vn}$	SZVRP3$_{tn}$	SZVRP2$_{tn}$	SZVRP4$_{n}$	SZVRP2$_{vn}$	SZVRP3$_{n}$	SZVRP2$_{n}$	SZVRP1$_{tn}$	Giant TSP$_{tn}$	SZVRP1$_{vn}$	SZVRP1$_{n}$	CW-SOCP

In Table B-9, we show the computation times for the 14 methods. SZVRP1$_n$ is the fastest overall, averaging about seven seconds per problem. SZVRP1$_{vn}$ and CW-SOCP are also fast, averaging less than 15 seconds per problem. The SZVRP3 and SZVRP4 variants are all slow, averaging between 370 and 1100 seconds per problem. For each k, of the two variants of SZVRPk that apply Phase IV (SZVRPk_{vn}, SZVRPk_{tn}), the VRP-based method is faster than the TSP-based method.

In Tables B-10 - B-12, we present the results for the 28 problems using the Manhattan norm. The 14 heuristics compared for the Euclidean norm are also used here. All SZH variants use the Manhattan norm to calculate distances in Phase I. As with the CETSP (see Section B.5), using the Euclidean norm to calculate distances in Phase I sometimes produces better tours and even better average deviations. However, for lack of room we present here only the results of methods that use the Manhattan norm in Phase I. In Appendix N and Appendix O, we give the best-known results from all our experiments for all problems. Many of the best-known results for the Manhattan norm indicate that the Euclidean norm was used in Phase I.

In Table B-10, we see that the four variants of SZVRP3 and SZVRP4 that apply the Phase IV post-processor (SZVRP3$_{vn}$, SZVRP3$_{tn}$, SZVRP4$_{vn}$, SZVRP4$_{tn}$) collectively produce 28 out of 28 best solutions. SZVRp4$_{tn}$, by itself, produces 15 best solutions.

Table B-9: Computation time for 28 problems with equal radius and 3D Euclidean norm

	SZVRP1$_n$	SZVRP1$_{vn}$	CW-SOCP	SZVRP2$_n$	SZVRP2$_{vn}$	Giant TSP$_{tn}$	SZVRP1$_{tn}$	SZVRP2$_{tn}$	SZVRP3$_n$	SZVRP3$_{vn}$	SZVRP3$_{tn}$	SZVRP4$_n$	SZVRP4$_{vn}$	SZVRP4$_{tn}$

Table B-11 gives the average deviation from the best solutions in Table B-10. Results are similar to those for the Euclidean norm. One method averages less than 1% deviation across all 28 problems (SZVRP4$_{tn}$). Four methods average less than 2% deviation across all problems (SZVRP4$_{tn}$, SZVRP3$_{tn}$, SZVRP3$_{vn}$, SZVRP4$_{vn}$). For SZVRP1 and SZVRP2, the TSP-based Phase IV variant produces better tours on average than the VRP-based Phase IV variant, the same as with the Euclidean norm. Giant TSP$_{tn}$ and CW-SOCP are again among the least accurate methods.

Average computation times are given in Table B-12. They are very similar to those for the Euclidean norm given in Table B-9. SZVRP1$_n$ is the fastest method, averaging about 8.5 seconds. CW-SOCP and SZVRP1$_{tn}$ follow, averaging less than 18 seconds. The variants of SZVRP3 and SZVRP4 that apply Phase IV are all very slow, averaging in excess of 400 seconds per problems. For each k except 4, SZVRPk_{vn} is faster than the SZVRPk_{tn}. This is consistent with the results using the Euclidean norm.

Over all 28 CEVRP benchmark problems using either norm, we observe the following. (1) In Section B.5, we saw that for the CETSP, methods that use the 3D$_{AN}$ Phase I algorithm are somewhat faster than those that use the 3D$_{NUM}$ Phase I algorithm but are less accurate. For the CEVRP, methods that apply 3D$_{AN}$ are both slower and less accurate than those that apply 3D$_{NUM}$ and were not included in the results. (2) Steiner-zone methods are clearly more accurate than CW-SOCP, which does not use Steiner zones. (3) For variants of the SZVRP1 and SZVRP2 methods, TSP-based Phase IV produces more accurate results than VRP-based Phase IV but is slower. TSP-based Phase IV is more accurate than VRP-based Phase IV

for SZVRP3 and SZVRP4 using the Manhattan norm but only for SZVRP4 using the Euclidean norm. (4) If we consider the ordering of the columns in the tables presenting average deviation and average computation time to be performance rankings, for the Euclidean norm, SZVRP2$_{vn}$ has the best average rank of 6. SZVRP2$_{n}$, SZVRP2$_{tn}$, and SZVRP3$_{vn}$ follow with an average rank of 6.5. For the Manhattan norm, six methods have an average rank of 6.5 (SZVRP3$_{vn}$, SZVRP3$_{tn}$, SZVRP4$_{tn}$, and the three SZVRP2 variants) followed by CW-SOCP, with an average rank of 7. Considering the results for both norms, SZVRP2$_{vn}$ has the best average rank for each norm. All SZVRP2 methods perform very well for each norm.

Table B-12: Computation time for 28 problems with equal radius and 3D Manhattan norm

	SZVRP1$_n$	CW-SOCP	SZVRP1$_{vn}$	SZVRP2$_n$	SZVRP2$_{vn}$	Giant TSP$_{tn}$	SZVRP1$_{tn}$	SZVRP2$_{tn}$	SZVRP3$_n$	SZVRP3$_{vn}$	SZVRP3$_{tn}$	SZVRP4$_{tn}$	SZVRP4$_{vn}$	SZVRP4$_n$

B.7 Conclusions

In this section, we extended the Steiner-zone heuristic to solve the CETSP and CEVRP in 3D. We developed two Phase I algorithms, one that tries to directly apply the 2D Phase I algorithm in 3D and the other that numerically approximates the boundary of the intersection of k spheres as it appears on the surface of one of them ($sphere_i$ where i is the base node). We applied numerous variants of the SZH to 28 benchmark CETSP problems and 28 benchmark CEVRP problems. We compared the results with those produced by two alternative heuristics for the CETSP and two alternative heuristics for the CEVRP. Our results indicate that Steiner-zone methods are more accurate than methods that do not use Steiner-zones. Some variants of SZH ($SZ2_{nu}$, $SZ3_{an}$, $SZVRP2_n$, $SZVRP2_{vn}$, $SZVRP2_{tn}$) balance accuracy and computational speed across all problems for both the Euclidean and Manhattan 3D norms.

Appendix C

The Steiner-Zone Heuristic (SZH) With Arbitrary Radius

In this appendix, we assume that the radius of each disk in a CETSP or CEVRP problem may be different ($r_i \neq r_j$). In Chapters 2 - 4, we described our benchmark problems as having equal radius. Here, we refer to problems with arbitrary radius.

To generalize the CETSP and CEVRP formulations given in Chapters 2 and 3, we replace r with r_i. Below, we generalize SZH to solve an arbitrary radius problem.

C.1 Phase I

If $r_i = r_j$ for all nodes i and j, then no node's disk will contain another node's disk unless two non-depot nodes have the same coordinates which we assume does not occur. This is not true when $r_i \neq r_j$ for at least one pair of nodes i and j. If $disk(i)$ contains $disk(j)$, any point inside $disk(j)$ visits i. Because the perimeter of $disk(j)$ does not intersect the perimeter of $disk(i)$, any Steiner zone based on node i cannot include node j. No upper and lower angles of intersection can be calculated. It is difficult to determine if $disk(j)$ intersects the $k-1$ other disks in the $SZ(k)$ based on node i. We show this in Figure C.1.

If $disk(j)$ contains $disk(i)$, then every point in any Steiner zone based on node

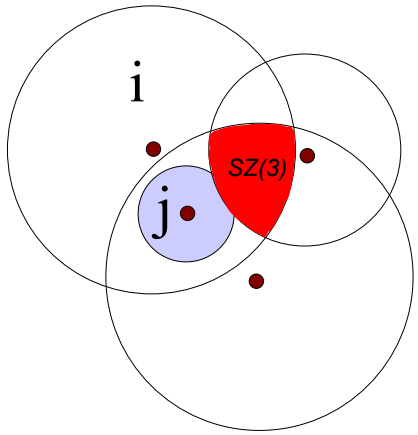

Figure C.1: $disk(i)$ contains $disk(j)$. $disk(j)$ intersects the $SZ(3)$ based on node i. The boundaries of $disk(i)$ and $disk(j)$ do not intersect, so we cannot calculate upper and lower angles of intersection with $disk(i)$. Without angles of intersection, there is no formula for obtaining a point that is feasible for all four disks although such a point exists. A feasible point would have to be calculated numerically.

i visits j. In Phase I, if node i is currently the first node in $list$, we set aside every node in $list$ whose disk contains $disk(i)$. After identifying the Steiner zone with largest degree that we can form with node i, we add to it all nodes whose disks contain $disk(i)$. If we are solving a CEVRP, we must ensure that adding disks that contain $disk(i)$ does not create a Steiner zone with a total demand exceeding the maximum vehicle capacity.

We apply the same modifications to SZH in 3D as in 2D, except that $sphere(i)$ replaces $disk(i)$.

C.2 Phase II

No changes to Phase II are required to apply SZH to a problem with arbitrary radius.

C.3 Phase III

Serious numerical issues can occur when we apply the Phase III SOCP exact solver to a problem with arbitrary radius. The constraint matrices are ill-conditioned meaning that a small change in a few coefficients leads to a very large change in the solution. In the presence of ill-conditioning, scaling the coefficients may alleviate the problem. For an equal-radius problem, we scale coefficients to lie within a unit square. Even with this scaling CPLEX often claims as optimal a solution that is not only suboptimal but highly infeasible. That is, the representative point returned as optimal for node i lies well beyond r_i units from node i.

In 2D, we have two options when we have an infeasible SOCP solution returned by CPLEX: (1) apply the IP_{PhIII} heuristic Phase III solver, which does not suffer from numerical issues but cannot be used when Phase IV is applied; (2) solve Phase III as a general NLP, which is computationally slow. In 3D, we have only the NLP option.

C.4 CETSP Results

We created benchmark problems for the CETSP and CEVRP with arbitrary radius by generating uniformly random radii for each node of the seven $TSPLIB$ problems (recall that there are only seven $TSPLIB$ TSP problems on which the 21 $TSPLIB$ CETSP and CEVRP problems given in previous chapters are based, and each is run with three different radius patterns) and the seven $Team$ problems. Radii are generated using a uniform distribution in the range $[0,\ b]$ where b is different

for each problem. The arbitrary radius problems are solved in 2D and 3D, using both the Euclidean and Manhattan norms. The results are ordered from left (best or fastest) to right (worst or slowest).

C.4.1 2D Euclidean CETSP

In Tables C-1, C-2, and C-3, we give the results for 10 heuristics on the 14 CETSP problems with arbitrary radius and 2D Euclidean norm. The 10 heuristics are described in detail in Chapters 2 and 4.

In Table C-1, we see that HYBRID2 produces four best solutions, SZ3 produces three best solutions, and GTSP2 produces three best solutions. SZ1 produces shorter tours than either YUAN+ or LK-SOCP for 12 of the 14 problems.

Table C-2 presents the average deviations (as percentages) from the best solutions in Table C-1. HYBRID2 and HYBRID1 are the most accurate heuristics over the 14 problems, averaging 1.24% and 1.89% deviation. YUAN+ and LK-SOCP both have large average deviations (13.71% and 14.09%, respectively).

Table C-3 gives computation times for the 10 heuristics across the 14 problems. SZ1 is very fast, averaging just over one second per problem. SZ2 is also quite fast (about 29 seconds per problem). LK-SOCP is much slower for problems with arbitrary radius than for problems with equal radius (compare with the results from Chapters 2 and 4), averaging over 200 seconds per problem. This is because the NLPs that must be solved for LK-SOCP are much larger than the NLPs that must be solved for Steiner-zone methods. The Steiner-zone methods reduce n nodes to m

Steiner zones. Steiner-zone methods solve Phase III for tours of $m \leq n$ points, but LK-SOCP and YUAN+ solve Phase III for tours of n points.

If we consider the column orderings in Tables C-2 and C-3 to be rankings, then SZ2 is the best heuristic, with an average rank of 2.5. HYBRID1 and HYBRID2 are next with an average rank of 3.5. SZ3, $SZ3_{50-59}$, LK-SOCP, and YUAN+ have an average rank of 6.

C.4.2 2D Manhattan CETSP

In Tables C-4, C-5, and C-6, we give the results for 14 heuristics on the 14 CETSP problems with arbitrary radius and 2D Manhattan norm. The results are similar to the results for the Euclidean norm. Ten of the heuristics are the same as in Section . Four heuristics ($SZ1_E$, $SZ2_E$, $SZ3_E$, $SZ3_{E\ 50-59}$) are subscripted with an E because they use the Euclidean norm during Phase I to order the list of nodes from which Steiner zones are created. For example, $SZ3_E$ is the same as SZ3 except that $SZ3_E$ uses the Euclidean norm in Phase I and uses the Manhattan norm only in Phases II, III, and IV, whereas SZ3 uses the Manhattan norm in all phases.

In Table C-4, we see that $SZ3_{E\ 50-59}$ produces five best solutions, SZ3 produces four best solutions, and $SZ3_E$ produces three best solutions. Table C-5 presents the average deviations (as percentages) from the best solutions in Table C-6. HYBRID2 and SZ3 are the most accurate heuristics over the 14 problems, averaging 1.24% and 1.59%, respectively. YUAN+ and LK-SOCP both have large average deviations (14.22% and 15.76%, respectively).

Table C-6 gives computation times for the 14 heuristics across the 14 problems. SZ1 and $SZ1_E$ are very fast, averaging about 1.1 seconds per problem. LK-SOCP, SZ2, and $SZ2_E$ are also fast, requiring between nine and 16 seconds, on average, to solve a problem. Although still slower than SZ1 and $SZ1_E$, LK-SOCP's computation times are much closer to the times produced by LK-SOCP in Chapter 2 than to the results in Section C.4.1.

If we consider the column orderings in Tables C-5 and C-6 to be rankings, SZ3

produces the best average ranking (4.5), followed by $SZ3_E$ and $SZ2_E$ (5.5).

Over all 14 problems, using both the 2D Euclidean and Manhattan norms, we observe the following. (1) Methods that do not use Steiner zones (LK-SOCP and YUAN+) are not very accurate for CETSP problems with arbitrary radius. (2) HYBRID2 is consistently the most accurate method. It does not produce the largest number of best solutions, but is not more than 5.05% from the best solution for any problem (3) SZ2 and $SZ2_E$ produce the best combination of speed and accuracy across all problems, needing between 10 and 30 seconds per problem with an average deviation between 1.94% and 2.72% from the best solutions. (4) We did not use the Phase IV + MAH heuristic ($SZ3_{0-360}$) here, running experiments only for the 50°-59°range ($SZ3_{50-59}$, $SZ3_{E\ 50-59}$). Our results indicate that for very large average computation times (up to 32,000 seconds), these methods do not substantially increase the accuracy of Phase IV methods (SZ3 and $SZ3_E$). A different 10° range may produce better tours on average than [50°, 59°], but it could also be that the MAH heuristic is not as effective for problems with arbitrary radius as it is for problems with equal radius.

C.4.3 3D Euclidean CETSP

We created 14 3D CETSP problems with arbitrary radius by adding the z-coordinates to the 2D problems in Section C.4.1 and Section C.4.2.

In Tables C-7, C-8, and C-9, we give the results for the 14 CETSP problems with arbitrary radius and 3D Euclidean norm. We applied the same six heuristics to these problems as are described and used in Appendix B. The subscripts $_{nu}$ and $_{an}$ refer to which version of Phase I in 3D is applied. They are described in Appendix B.

In Table C-7, we see that SZ3$_{nu}$ produces 12 best solutions and SZ3$_{an}$ produces two best solutions. Of the two SZH methods that do not apply Phase IV, SZ2$_{nu}$ produces better solutions than SZ2$_{an}$ in eight problems. SZ2$_{an}$, SZ3$_{an}$, and SZ3$_{nu}$ produces solutions at least as good as those produced by YUAN+ and LK-SOCP for all problems. SZ2$_{nu}$ produces better solutions than YUAN+ and LK-SOCP 11 of 14 problems.

In Table C-8, we compare the average deviations from the best solutions given in Table C-9 for each of the six methods. The four SZH methods are more accurate than the methods that do not use Steiner zones (YUAN+, LK-SOCP), with an average deviation between 7.64% and 17.49% less than YUAN+ and LK-SOCP's average over all 14 problems. Specifically, SZ2$_{an}$ has the highest average deviation (9.44%) of the four SZH methods, and YUAN+ (17.18%) has the lower average of the methods that do not use Steiner zones. The difference is 7.64%. SZ3$_{nu}$ has the lowest average (0.03%) of the SZH methods, and LK-SOCP has the largest average

(17.52%) of the methods that do not use Steiner zones. The different is 17.49%. Similarly, the SZH methods that use the $3D_{NUM}$ Phase I method ($SZ2_{nu}$, $SZ3_{nu}$) have an average deviation between 2.66% and 9.41% smaller than the SZH methods that use $3D_{AN}$ to solve Phase I. On the 14 problems in Table C-8, $SZ3_{nu}$ is the most accurate method with an average deviation of 0.03%.

In Table C-9, we give the computation times for the six methods on the 14 problems. None of the methods is very fast. $SZ2_{nu}$ is the fastest, averaging about 146 seconds for each problem, with YUAN+ and LK-SOCP following closely, averaging between 250 and 300 seconds per problem. $SZ3_{an}$ and $SZ3_{nu}$ are very slow, averaging between 17,000 and 22,000 seconds, although $SZ3_{nu}$ is faster than $SZ3_{an}$. It appears to be an anomaly that LK-SOCP is slower on average than YUAN+ (this does not occur elsewhere in the dissertation) since the methods are the same except that YUAN+ solves Phase II to optimality (slower) whereas LK-SOCP solves Phase II approximately (faster). The difference in time occurs during Phase III.

C.4.4 3D Manhattan CETSP

In Tables C-10, C-11, and C-12, we give the results for the 14 CETSP problems with arbitrary radius and 3D Manhattan norm. We coded eight heuristics to solve these problems. These heuristics, along with $3D_{NUM}$ and $3D_{AN}$, are described in Appendix B.

In Table C-10, we see that $SZ3_{nuEuc}$ produces best solutions for 8 of 14 problems, and $SZ3_{nu}$ produces 5 best solutions. Of the SZH methods that apply Phase IV, methods that apply $3D_{NUM}$ in Phase I ($SZ3_{nuEuc}$, $SZ3_{nu}$) produce better solutions than both methods that apply $3D_{AN}$ ($SZ3_{anEuc}$, $SZ3_{an}$) on 12 of 14 problems. When Phase IV is not applied, $SZ2_{nu}$ (using $3D_{NUM}$) produces solutions that are no worse than solutions produced by $SZ2_{an}$ (using $3D_{AN}$) on all problems. YUAN+ and LK-SOCP produces poorer solutions than any SZH method on all 14 problems.

In Table C-11, we compare the average deviations from the best solutions given in Table C-10 for each of the eight methods. The six SZH methods are more accurate than the methods that do not use Steiner zones (YUAN+, LK-SOCP), with an average deviation between 9.18% and 16.22% less than that of YUAN+ and LK-SOCP. Of the SZH methods that apply Phase IV, those that use the $3D_{NUM}$ Phase I method ($SZ3_{nu}$, $SZ3_{nuEuc}$) are more accurate (by at least 1%) than those that use $3D_{AN}$ ($SZ3_{an}$, $SZ3_{anEuc}$). For SZH methods that do not apply Phase IV ($SZ2_{nu}$, $SZ2_{an}$), the results are different: $SZ2_{an}$ (using $3D_{AN}$) is more accurate than SZ_{nu} (using $3D_{NUM}$) by at least 1% (5.96% vs. 7.16%) over all problems.

In Table C-12, we give the computation times for the eight methods on the

14 problems. LK-SOCP is reasonably fast, averaging almost 37 seconds per problem. YUAN+ and $SZ2_{nu}$ have reasonable computation times (roughly 111 and 732 seconds). The remaining methods are all very slow, averaging in excess of 2,300 seconds per problem.

Over all 14 arbitrary radius problems, solved using the 3D Euclidean and Manhattan norms, we observe the following. (1) Methods that do not use Steiner zones are less accurate than SZH methods. (2) Solution times are substantially slower than solution times for the equal radius 3D problems (see Appendix B). This

is because we are forced to use a general NLP solver in Phase III to guarantee feasible solutions (SOCP infeasibility due to ill-conditioned matrices was described in Section C.3). The NLP solver is much slower than the SOCP solver. (3) The $3D_{NUM}$ Phase I method is more accurate than $3D_{AN}$ (except for problem $rat195$ using the Manhattan norm). (4) When using the Manhattan norm, creating the ordered list of nodes in Phase I using the Euclidean norm produces better solutions on average than using the Manhattan norm. (5) When Phase IV is not applied, using $3D_{NUM}$ ($SZ2_{nu}$) is much faster than using $3D_{AN}$ ($SZ2_{an}$). This is because the problem size reduction achieved in Phase I using $3D_{NUM}$ is typically much greater than that achieved using $3D_{AN}$. When Phase IV is applied, $3D_{NUM}$ is two to four times faster for problems with the Manhattan norm but about 1.3 times slower for problems with the Euclidean norm. (6) If we consider the columns in the tables giving average deviations and computation times to be rankings, then $SZ2_{nu}$ is the most competitive heuristic, having the best average rank for both the Euclidean

norm (1.5) and the Manhattan norm (2.5). This ranking is consistent with the rankings for the equal radius CETSP problems solved using both 3D norms (see Appendix B) where $SZ2_{nu}$ has the highest average rank for the Euclidean norm and the second highest rank for the Manhattan norm).

C.5 CEVRP Results

C.5.1 2D Euclidean CEVRP

In Tables C-13 - C-15, we give results for 14 CEVRP arbitrary radius benchmark problems with 2D Euclidean norm. We coded the 15 heuristics described in Chapters 3 and 4.

In Table C-13, we give the tour lengths produced by each method. We see that $SZVRP3_{t50-59}$ produces six best solutions and $SZVRP4_t$ produces four. The average deviations from the best solutions in Table C-13 are given as percentages in Table C-14. $SZVRP3_{t\ 50-59}$, $SZVRP4_t$, and SZVRP4 have an average deviation less than 2%. Five SZH variants have averages less than 5% (SZVRP4, SZVRP3, $SZVRP4_v$, $SZVRP2_{t50-59}$, and $SZVRP3_v$). SZVRP1, GTSP-VRP, Giant TSP, and CW-SOCP have average deviations that exceed 9%.

In Table C-15, we give the computation times for the 15 heuristics. SZVRP1 is the fastest method, averaging about seven seconds per problem. CW-SOCP, SZVRP2, Giant TSP, and $SZVRP2_v$ are fast, averaging 10 to 40 seconds per problem. Nine methods take over 100 seconds per problem and seven methods take at least 1,000 seconds.

If we consider the column orderings to be performance rankings, SZVRP3 has the best average rank (5.5) followed by SZVRP4 (5.5) and SZVRP2 (6).

C.5.2 2D Manhattan CEVRP

In Tables C-16 - C-18, we give results for 14 CEVRP arbitrary radius benchmark problems with 2D Manhattan norm. We coded the same 15 heuristics given in Section C.5.1 except that the Manhattan norm is used in every phase.

In Table C-16, we give the tour lengths produced by each method. We see that SZVRP4$_t$ produces four best solutions and SZVRP3$_{t50-59}$ produces three. SZVRP4$_v$, SZVRP4, and SZVRP3 produce two each. The average deviations from the best solutions in Table C-16 are given as percentages in Table C-17. Both variants of SZVRP4 that apply Phase IV (SZVRP4$_v$, SZVRP4$_t$) have an average deviation less than 2% across the 14 problems. Seven variants of SZH produce average deviations less than 5%. CW-SOCP, which does not use Steiner zones, has the highest average deviation (15.57%).

In Table C-18, we give the computation times for each method. CW-SOCP and SZVRP1 are both fast, averaging five to five and a half seconds per problem. SZVRP2, Giant TSP, SZVRP2$_v$, and SZVRP2$_t$ have an average less than 100 seconds per problem. Nine methods have an average over 190 seconds per problem.

If we consider the column orderings to be performance rankings, then SZVRP3 and SZVRP3$_t$ have the best average rank (6) followed by SZVRP4$_v$ (6.5). SZVRP2, SZVRP2$_v$, SZVRP2$_t$, and SZVRP3$_v$ each have an average rank of 7.

Over all 14 CEVRP problems, using both the 2D Euclidean and Manhattan norms, we observe the following. (1) The method that does not use Steiner zones (CW-SOCP) does not produce good results for arbitrary radius problems. (2) Based on the results using the 50°-t9° range, MAH heuristics do not add substantial accuracy to SZH methods for arbitrary radius CEVRP problems. (3) Variants of SZVRP2 and SZVRP3 combine accuracy and computational speed better than SZVRP1, SZVRP4, and the non-SZH methods.

C.5.3 3D Euclidean CEVRP

We created 14 3D CEVRP problems with arbitrary radius by adding the z-coordinates to the 2D problems in Section C.5.1 and Section C.5.2. In Tables C-19, C-20, and C-21, we give the results for the 14 CEVRP problems with arbitrary radius and 3D Euclidean norm. We use the same 14 heuristics given in Appendix B.

In Table C-19, we see that SZVRP4$_{tn}$ and SZVRP3$_{vn}$ together produce 10 best solutions. CW-SOCP produces only one best solution. The average deviation from the best solutions in Table C-19 is given as a percentage in Table C-20. We see that SZVRP4$_{tn}$ is the most accurate method with an average deviation less than 1%. All variants of SZVRP3 and SZVRP4, along with SZVRP2$_{tn}$ have an average deviation less than 3%. Giant TSP$_{tn}$, CW-SOCP, and the variants of SZVRP1 produce average deviations between 6% and 10.50%.

Computation times are given in Table C-21. CW-SOCP has an average of 25

seconds per problem. SZVRP1$_n$ and SZVRP2$_n$ average less than 100 seconds per problem. Seven SZVRP methods along with Giant TSP$_{tn}$ are very slow, averaging more than 1,000 seconds per problem. Though not as slow as the CETSP heuristics given in Section C.5, the computation times are still much slower than those for equal radius problems. This is because of the numerical difficulties encountered by CPLEX when solving the SOCP formulation for arbitrary radius. When CPLEX returns an infeasible solution, we resolve Phase III as a general NLP which can be very slow. The times given in Table C-21 are faster than the times for the equivalent CETSP problems because each route in the CEVRP generally has fewer nodes than the single route in the CETSP problems. The Phase III NLP is solved more quickly for k small routes with a total of n nodes than for one large route with n nodes.

If column order in Tables C-20 and C-21 is considered a ranking, then SZVRP4$_{vn}$ has the best average rank (5.5) followed by SZVRP2$_n$ (6) and SZVRP2$_{vn}$ and SZVRP3$_n$ (6.5).

C.5.4 3D Manhattan CEVRP

In Tables C-22 - C-24, we provide results for the same 14 CEVRP problems given in Section C.5.3 where we use the Manhattan norm instead of the Euclidean norm.

In Table C-22, we see that SZVRP4$_{tn}$ and SZVRP3$_{tn}$ together produce 11 best solutions. CW-SOCP does not produce any best solutions. The average deviations from the best solutions in Table C-22 are given as a percentage in Table C-23. We see that SZVRP4$_{tn}$ is the most accurate method with an average deviation of less than 1%. All variants of SZVRP3 and SZVRP4, along with SZVRP2$_{tn}$ have an average deviation less than 4%. Giant TSP$_{tn}$, CW-SOCP, and the variants of SZVRP1 produce average deviations between 7.5% and 12.50%.

Computation times are given in Table C-24. They are similar to those for the Euclidean norm. CW-SOCP is the fastest with an average of 22 seconds per problem. SZVRP1$_n$ and SZVRP2$_n$ have an average between 50 and 90 seconds per problem. Eight SZVRP methods along with Giant TSP$_{tn}$ are very slow, averaging more than 700 seconds per problem. SZVRP4$_n$ is the slowest method, averaging almost 2,300 seconds per problem. SZVRP4$_n$, which does not apply Phase IV, is slower than the two variants of SZVRP4 that apply Phase IV. The slower times of SZVRP4$_{tn}$ and SZVRP4$_{vn}$ can be attributed to the high variability in computation time when solving Phase III as a general NLP.

If the column orderings in Tables C-23 and C-24 are considered to be rankings, then SZVRP2 and SZVRP4$_{tn}$ have the best overall average rank (6) followed by

SZVRP2$_{tn}$, SZVRP2$_{vn}$, SZVRP3$_{vn}$ (6.5).

Over all 14 CEVRP benchmark problems using both the 3D Euclidean and 3D Manhattan norms, we see the following. (1) Methods that use Steiner zones are consistently more accurate than CW-SOCP, which does not use Steiner zones. (2) In 7 out of 8 cases (the only exception being SZVRP3 with the Euclidean norm), TSP-based Phase IV produces more accurate tours, on average, than VRP-based Phase IV. VRP-based Phase IV is substantially faster than TSP-based Phase IV. For equal radius 3D CEVRP problems, the difference was much closer. The large disparity in computation times for arbitrary radius 3D CEVRP problems is due to the fact that TSP-based Phase IV replaces more Steiner zones with duple and singleton Steiner zones at each iteration. This creates larger routes to which Phase III must be applied. We recall that Phase IV is finished when there is no improvement after 4 iterations or only singletons and duples remain. VRP-based Phase IV replaces fewer Steiner zones per iteration meaning that more iterations would be required to have only singletons and duples. Therefore, VRP-based Phase IV must reach a local minimum from which is cannot escape faster than TSP-based Phase IV.

C.6 Conclusions

In this appendix, we extended the Steiner-zone heuristic to solve CETSP and CEVRP problems where each disk can have a different radius. We created and solved benchmark problems in 2D and 3D, using the Euclidean and Manhattan norms. We found that the numerical difficulties associated with solving Phase III to optimality led to very large increases in computation time for Steiner-zone methods as well as

moderate increases in computation time for methods that do not use Steiner zones (LK-SOCP, YUAN+, CW-SOCP). As opposed to equal radius problems, where LK-SOCP, YUAN+, and CW-SOCP produced excellent results quickly for certain types of problems (high-overlap ratio problems), methods that do not apply Phase I have large average deviations for the majority of problems. Over all problems, variants variants of SZ2, SZVRP2, and SZVRP3 exhibit the best balance of accuracy and computation speed for the methods studied in this appendix.

Appendix D

The IP_{PhIII} Heuristic

The shortest path problem solved at each iteration is formulated as a minimum-cost network flow problem. Each Steiner zone is approximated by k points (we use $k = 3$). The source (depot) is given an artificial supply of 1 unit and the sink (a dummy copy of the depot) is given a demand of 1 unit. The k points approximating each Steiner zone are transhipment nodes. Arc costs are distances between points. We show the structure of the network in Figure D.1. The constraint matrix of a network flow problem with this structure is totally unimodular [72], and the righthand-side values are integer. We can solve each network flow problem as a linear program and produce integer solutions.

The first two iterations of the IP_{PhIII} integer program establish a bounded region on each Steiner zone's perimeter that is likely to contain the optimal TSZP location for each Steiner zone's representative point. In subsequent iterations, the solution converges to a near-optimal TZSP tour. The bounded region defined by

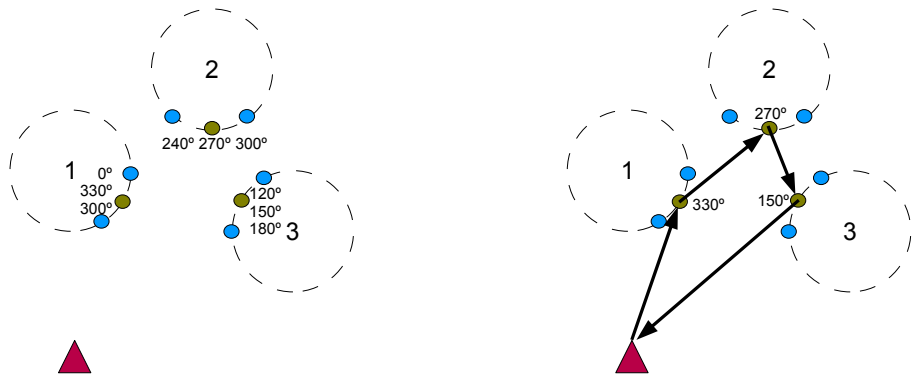
iterations 1 and 2 and refined in iterations 3 and 4 sometimes does not contain the optimal representative point for some Steiner zones. Iteration 5 is the first iteration where this can be recognized. We shift these bounded regions so that the heuristic converges good representative points. We discuss iteration 5 in greater detail. Using the example problem in Figure D.2(a), we now show how IP_{PhIII} converges.

In Figure D.2(a), we show the results of applying Phase II to a problem with one depot and three Steiner zones of degree 1 (typically, Steiner zones have degree greater than 1 and are not disks; we use disks here for simplicity.). Each Steiner zone is approximated by k points on its perimeter. In our example, $k = 3$. The location of these points is 0°, 120°, and 240°, where the degree refers to the polar angle relative to the SZ's representative point. We show this in Figure D.2(b). The angle size between two neighboring points is denoted θ. Initially, $\theta = 120°$ but decreases as the number of iterations increases. In this example, each Steiner zone's representative point is the origin of the disk. Typically, each representative point fixed in Phase II will not be the center of its Steiner zone. The tour order is depot-1-2-3-depot. An iteration of IP_{PhIII} minimizes the tour distance such that one of the k points in each SZ is visited. The Steiner zones are visited in the order determined by Phase II. The solution to this example is shown in Figure D.2(c) where the points at 0°, 240°, and 120° were chosen for Steiner zones 1, 2, and 3. This represents the first iteration of IP_{PhIII}. Computational experiments suggested that values of k larger than three do not converge to better solutions and only slow the algorithm. We set $k = 3$ in the remainder of this chapter.

A single iteration of IP_{PhIII} does not lead to a good approximation of the



(a) Possible solution points for iteration 3

(b) Solution to iteration 3

Figure D.4: Iteration 3

TSZP. Therefore, we use an iterative strategy by which a succession of IPs converge to a near-optimal value for the TSZP. As discussed previously, in iteration 1, we approximate each Steiner zone by three points, located at 0°, 120°, and 240°. We set aside the solution of iteration 1 for use in iteration 3. In iteration 2, we approximate each Steiner zone by three points located at 60°, 180°, and 300°. For this example, the solution to iteration 2 is shown in Figure D.3(a) where the points at 300°, 300°, and 180° were chosen for Steiner zones 1, 2, and 3. The two solution points in each Steiner zone are spaced 60° apart relative to the representative point. Thus, $\theta = 60°$ after iteration 2.

After the first two iterations, we now have two possible solution points for each Steiner zone that act as upper and lower bounds on the final value for each SZ's representative point. In iteration 3, we begin an iterative process that converges to a near-optimal solution. For any SZ_i, two of the three possible points for the current iteration are the solution points from the prior two iterations. In general, the third point for SZ_i is the point at the polar angle bisecting the other two. In Figure

(b) Solution to iteration 4

Figure D.5: Iteration 4

D.4(a), we show the three points for each Steiner zone that are used in iteration 3. The bisecting angles are 330°, 270°, and 150° for Steiner zones 1, 2, and 3. The solution to iteration 3 is shown in Figure D.4(b) where the points at 330°, 270°, and 150° were chosen for Steiner zones 1, 2, and 3.

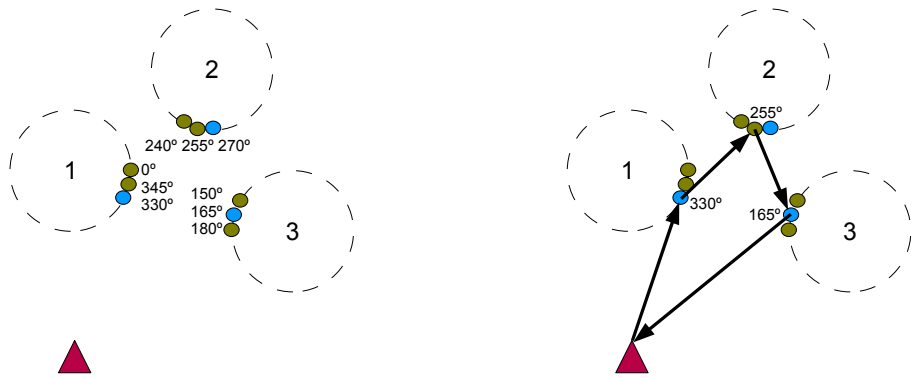
It is possible for the same point to be chosen for a particular Steiner zone in iterations 2 and 3 or any other pair of consecutive iterations except for 1 and 2. We call these situations ties and, except in iteration 5, we handle them by choosing two new points for that Steiner zone. The two new points are equally spaced $\pm(\frac{\theta}{\alpha})^\circ$ around the tie point. In early iterations, $\alpha = 1$ to ensure that a large enough section of the Steiner zone is being checked. In later iterations, or when the Steiner zone is extremely small and its Phase II representative point is on or nearly on the Steiner zone's perimeter, a larger $\frac{\theta}{\alpha}$ is needed to ensure that points are far enough apart to avoid missing a solution point.

We show the possible points for iteration 4 in Figure D.5(a). In SZ_1, the prior two iterations had solution points at 330° and 300°. Therefore, the third point for

this Steiner zone is at the polar angle of 315°($\theta = 15°$). Similarly, the third points for SZ_2 and SZ_3 are at the angles 285° and 165°. It appears that we ignore the results of iteration 1; however, we consider these results in iteration 5. The solution to iteration 4, given in Figure D.5(b), shows that points at 330°, 270°, and 165° were selected for Steiner zones 1, 2, and 3.

In iteration 5, we choose points differently than in previous iterations to avoid convergence to incorrect representative points. For SZ_1 and SZ_2, ties occur. In each case, the point that is selected is the point closest to solution point found in iteration 1. This indicates that we incorrectly ignored the result of iteration 1 for these two Steiner zones. Therefore, in iteration 5, for SZ_1 and SZ_2, instead of using the procedure for handling ties described above, we use the point selected in the previous iteration and the point from iteration 1 along with the point at the bisecting angle. For SZ_3, unlike the other two SZs, the solution points for the prior two iterations are different, 150°and 165°, indicating that we could ignore the result of iteration 1 for this Steiner zone. However, because we are in iteration 5, instead of choosing the point at the bisecting angle, 157.5°, as we do in other iterations, we choose the point at 180° as the third point. This ensures that we account for the case when the globally optimal point lies between 165° and 180°. The possible points for iteration 5 are shown in Figure D.6(a). The solution is shown in Figure D.6(b) where points at 330°, 255°, and 165° were chosen for Steiner zones 1, 2, and 3.

For all subsequent iterations, the rule for choosing the third point to represent each Steiner zone remains the same as before iteration 5: when the solution points



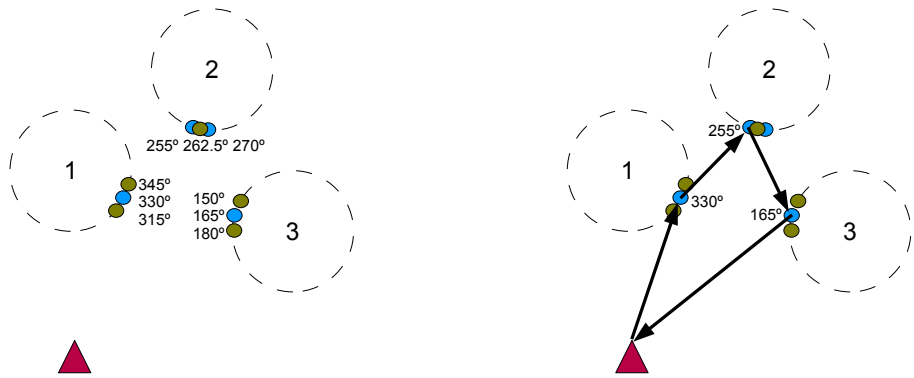
(a) Possible solution points for iteration 5

(b) Solution to iteration 5

Figure D.6: Iteration 5

for the prior two iterations are different for a particular Steiner zone, the third point is at the bisecting angle. If the points selected in the prior two iterations are the same for a given Steiner zone (a tie), then we select two new points for that Steiner zone in the next iteration. The two new points are equally spaced $\pm(\frac{\theta}{\alpha})^\circ$ around the tie point where $\alpha = 1$, 2, or 4, depending on the iteration. For example, we show the possible points for iteration 6 in Figure D.7(a). SZ_1 and SZ_3 both chose the same points in iterations 4 and 5. For SZ_1, this is the point at 330°, and thus, the two other points used in iteration 6 for SZ_1 are at 315°and 345°($\theta = 15°$). SZ_2 selected different points in iterations 4 and 5 (255° and 270°) and, therefore, for iteration 6, the third point will be the point at the bisecting angle, 265°. We show the solution to iteration 6 in Figure D.7(b).

In iterations 7 and 8, shown in Figures D.8 and D.9, it is clear that the heuristic is converging to a near-optimal solution of the TSZP. Note that the point selected for SZ_3 has not changed in several iterations. At each iteration, the two points selected around a tie point get progressively closer to the tie point, that is, θ is



(a) Possible solution points for iteration 6

(b) Solution to iteration 6

Figure D.7: Iteration 6

halved at each iteration. Eventually, either the tie is broken, or the tied point is the best representative point for that Steiner zone.

The solution to iteration 3 should be close to, if not exactly the same as, the solution of one iteration of IP_{PhIII} with $k = 12$ and $\theta = 30°$. Similarly, the solution to the fourth iteration should be very close to that of one iteration of IP_{PhIII} with $k = 24$ and $\theta = 15°$, the fifth, $k = 48$ and $\theta = 7.5°$, and so on. After 10 iterations, the solution should closely approximate the solution of one iteration of IP_{PhIII} for $k = 1536$. That is, the solution to the tenth iteration is equivalent to approximating each Steiner zone with a 1536-sided polygon and finding a near-optimal solution to the resulting TPP. Because each Steiner zone is always approximated by $k = 3$ points, the size of the IP remains constant for all iterations.

In Figure D.10, we show the solution to iteration 30. In our experiments, the heuristic converges to three or four decimal places after 10 iterations but may be run as many times as needed to achieve the desired numerical precision. IP_{PhIII} solves problems with up to 1001 nodes in under 1 CPU second. IP_{PhIII} solves most

(a) Possible solution points for iteration 8

(b) Solution to iteration 8

Figure D.9: Iteration 8

problems to optimality and is never more than 1% from optimality when it fails.

The IP_{PhIII} was designed for 2D problems (equal radius or arbitrary radius, Euclidean and Manhattan norm) where there the Steiner zones found in Phase I are disjoint or nearly disjoint. When there is too much overlap of Steiner zones, IP_{PhIII} produces very poor results and slows down substantially. We have not extended IP_{PhIII} to work in 3D.

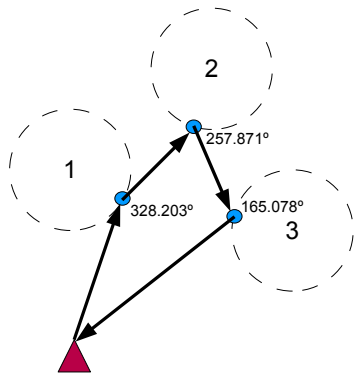

Figure D.10: The final result (iteration 30).

Appendix E

Formulation of the Touring Steiner Zones Problem as a Second-Order Cone Program

In this appendix, we formulate the Touring Steiner Zones Problem (TSZP) used to solve Phase III of the Steiner-zone heuristic to optimality as a second-order cone program (SOCP). The TSZP is the same problem as the Touring Polygons Problem (TPP) studied by Dror et al.[29] except that we consider convex regions whose boundaries are arcs of disks (Steiner zones) rather than polygons.

Let (a_i, b_i) be the origin of node i, $orig(i)$. We define r_i as the radius of the disk around node i, $disk(i)$. The binary variable e_{ij} represents the edge between nodes i and j. The sequence of Steiner zones in the tour is fixed in Phase III so that $j = i + 1$ for $i = 0, \ldots, (n-1)$ and $j = 0$ for $i = n$. Steiner zone m is denoted SZ_m. We now present the formulation.

$$\text{Minimize} \sum_{i,j} d_{ij} \tag{E1}$$

subject to

$$dX_{ij} - (x_i - x_j) = 0 \qquad i = 0, \ldots, n \tag{E2}$$

$$dY_{ij} - (y_i - y_j) = 0 \qquad i = 0, \ldots, n \tag{E3}$$

$$d_{ij}^2 - (dX_{ij}^2 + dY_{ij}^2) \leq 0 \qquad i = 0, \ldots, n \tag{E4}$$

$$(x_m - a_i)^2 + (y_m - b_i)^2 \leq r_i^2 \qquad \forall\ \mathrm{SZ}_m,\ i \in\ \mathrm{SZ}_m \tag{E5}$$

$$d \geq 0;\ dX,\ dY,\ x,\ y \text{ free};\ e \in \{0, 1\} \tag{E6}$$

The objective function (E1) minimizes the total distance of the tour found in Phase II. We include d_{ij} in the sum only when e_{ij} is an edge in the tour, that is, $e_{ij} = 1$. Similarly, all variables subscripted with ij appear only when the associated edge is in the tour produced by Phase II. The objective function is linear. Constraints (E2), (E3), and (E4) define the edge length variables, d_{ij}, such that the objective function can be written linearly. Second-order cone constraints may contain quadratic terms but cannot have mixed terms such as $x_i x_j$. Therefore, we use the dX, dY, and d variables. In (E2) and (E3), dX_{ij} and dY_{ij} define the difference variables for x_i and x_j and for y_i and y_j, respectively. Constraint (E4) expresses the distance squared, d_{ij}^2, as less than or equal to the sum of the squared x and y differences. SOCP formulations require constraints with quadratic terms to be expressed as inequalities rather than equalities. The minimization pushes this constraint towards equality so that the squared distance variable will approximate the squared Euclidean norm within a specified tolerance. Constraint (E12) requires node i's representative point to lie within the Steiner zone m of which it is a member.

The SOCP formulation can be extended to solve problems using the Manhattan norm. Constraint (E4) is dropped and constraints (E2) and (E3) are modified

to calculate the absolute value of the differences in x and y values, that is,

$$-dX_{ij} + (x_i - x_j) \leq 0 \qquad i = 0, \ldots, n \tag{E7}$$

$$-dX_{ij} + (x_j - x_i) \leq 0 \qquad i = 0, \ldots, n \tag{E8}$$

$$-dY_{ij} + (y_i - y_j) = 0 \qquad i = 0, \ldots, n \tag{E9}$$

$$-dY_{ij} + (y_j - y_i) = 0 \qquad i = 0, \ldots, n \tag{E10}$$

The SOCP formulation can be extended to solve problems using either norm in 3D. Node i's origin, $orig(i)$, is now represented by a triple, (a_i, b_i, c_i). We define r_i as the radius of the sphere surrounding node i, $sphere(i)$. The difference in z-coordinates for edge e_{ij} is represented by the continuous variable, dZ_{ij}, in constraint (E11):

$$dY_{ij} - (y_i - y_j) = 0 i = 0, \ldots, n \tag{E11}$$

Each representative point must lie within a three-dimensional Steiner-zone so that constraint (E12) is rewritten as:

$$(x_m - a_i)^2 + (y_m - b_i)^2 + (z_m - c_i)^2 \leq r_i^2 \qquad \forall \text{ SZ}_m,\ i \in \text{ SZ}_m \tag{E12}$$

Using the Manhattan norm in 3D, we add

$$-dZ_{ij} + (z_i - z_j) \leq 0 \qquad i = 0, \ldots, n \tag{E13}$$

$$-dZ_{ij} + (z_j - z_i) \leq 0 \qquad i = 0, \ldots, n \tag{E14}$$

to constraints (E7)-(E10).

The SOCP formulation solves Phase III of SZH to optimality and can handle arbitrary amounts of disk overlap. In computational experiments, CPLEX solved

100-node TSZPs in less than 1 second and 1000-node TSZPs in roughly 6 seconds. However, solution times grow rapidly as n grows. A 13,509-node TSZP is solved in roughly 300 seconds. In addition to longer solution times, the interior-point solver used by CPLEX to solve SOCPs is prone to numerical difficulties. For problems with a large variance among the values of r_i, CPLEX returns an infeasible solution due to ill-conditioning in the constraint matrix. Even when $r_i = r_j$ for all nodes i and j, the TSZP coefficients must be scaled to avoid ill-conditioning.

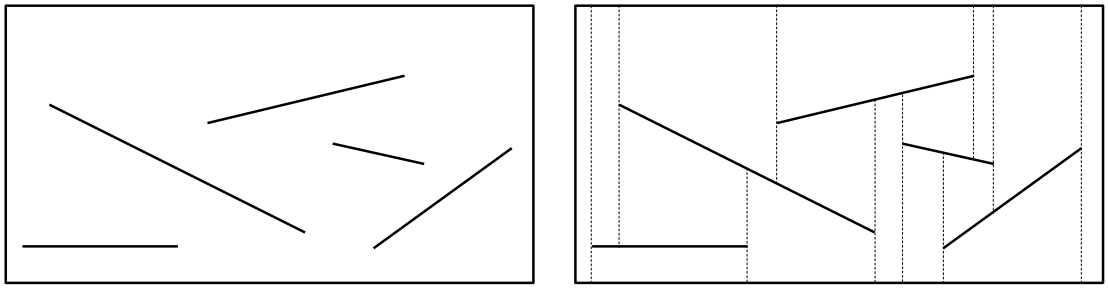
We note that our SOCP formulation can solve the general TPP to optimality with convex, possibly intersecting polygons presented in Dror et al. [29] by replacing constraint (E12) with the appropriate linear constraints describing each polygon.

Appendix F

Circular Trapezoidal Decomposition

Given a bounded rectangle containing a set, S, of non-intersecting lines, each non-vertical with unique endpoints, the rectangle can be decomposed into a set of contiguous trapezoids. A vertical line (bullet path) is extended from each endpoint and stops only when it hits a line from S or the rectangle. We show a rectangle and a set S in Figure F.1(a) and the resulting decomposition in Figure F.1(b). This decomposition is constructed efficiently with the randomized incremental algorithm introduced by Mulmuley [55] and is stored using a data structure called a history directed acyclical graph or history DAG. With this structure, one can answer point-location queries in $O(\log n)$ time. The algorithm is used frequently in the computational geometry field.

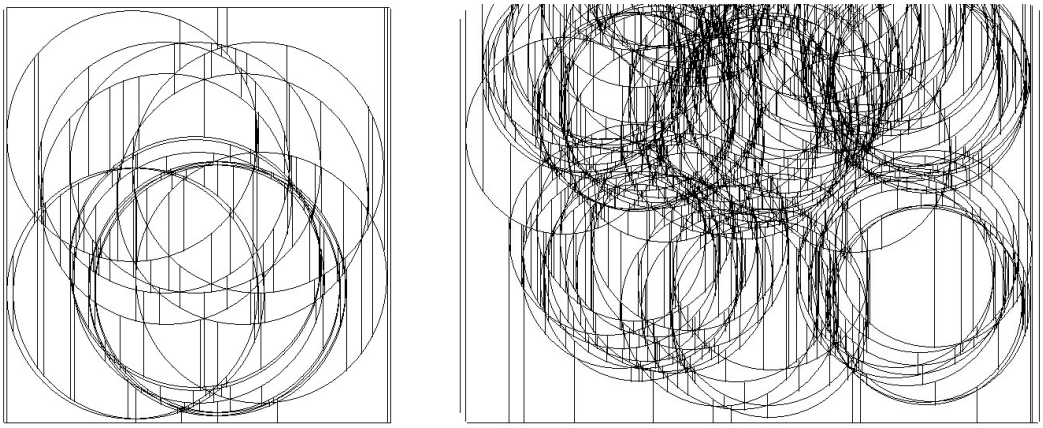
Trapezoidal decomposition can be extended to the case where the lines intersect and have non-unique endpoints. The lines in S can be replaced by a set, C of upper and lower hemisphere perimeters such that the union of each pair of perimeters is a disk. We call this circular trapezoidal decomposition (CTD) and show two examples in Figure F.1. The resulting trapezoids are replaced by regions whose bottom and top boundaries are either arcs from a disk or the bounding rectangle. The left and right boundaries remain vertical bullet paths. Each disk in a CETSP or CEVRP problem can be divided into an upper and lower hemisphere perimeters.



(a) A bounding rectangle containing five non-intersecting, non-vertical lines with unique endpoints.

(b) The region decomposed into 16 trapezoids.

Figure F.1: An example of trapezoidal decomposition. The dashed vertical lines are called bullet paths.



(a) An example with 18 disks

(b) Detail from problem pcb442 from TSPLIB with $r = 25$ for all disks.

Figure F.2: Two examples of the circular trapezoidal decomposition of a graph of disks.

We can apply circular trapezoidal decomposition to the C producing contiguous, non-overlapping regions. The number of disks overlapping in each region (degree) can be computed. We can order the entire list of regions by degree and greedily choose the regions with the highest degree to serve in Phase II and Phase III of SZH.

Some regions found by CTD may be contained entirely in the interior of one or more disks. We know of no closed form expression to obtain a feasible point for

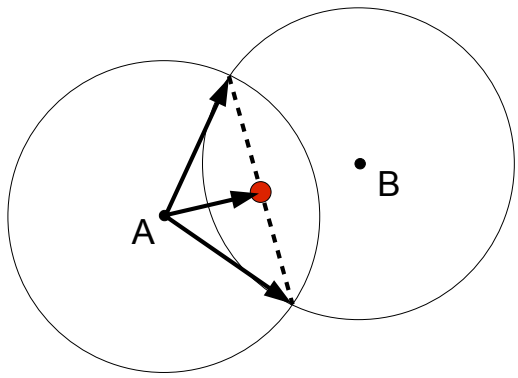


Figure F.3: The base node for this SZ is A. The perimeter of $disk(B)$ has at most two points of intersection with the perimeter of $disk(A)$. The representative point is the midpoint of the chord that connects the two points of intersection.

such regions using the method described in Phase II of SZH. Figure F.3 depicts how a feasible point is found when a node of origin is known for a particular Steiner zone. The convex hull of a $SZ(k)$ found by our Phase I heuristic has one side from each of its k component nodes. In Figure F.4 we show what a possible region found by circular trapezoidal decomposition looks like. The lens-shaped region is the intersection of $disk(A)$, $disk(B)$, and $disk(C)$. If we designated node C the origin of this $SZ(3)$, we would find an infeasible point using the method shown in Figure F.3. The angles of intersection between C and A do not overlap those of C and B. This is because $disk(C)$ contains the $SZ(3)$ in its interior. $disk(C)$ does not share any of the Steiner zone's convex hull. If, however, we knew *a priori* that either node A or node B was the origin, then we could correctly calculate a feasible point using the Phase II method shown in Figure F.3. CTD does not know which of the intersecting disks should be the node of origin for each region it creates. Therefore, the centroid of every region created by the CTD algorithm is saved as a feasible

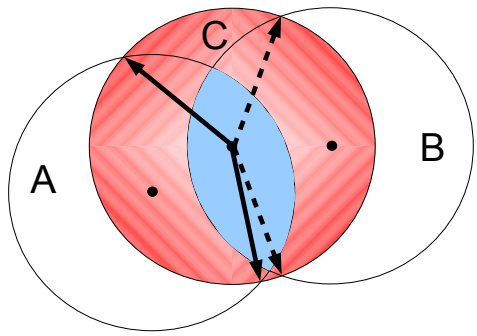

Figure F.4: The lens-shaped region is the intersection of $disk(A), disk(B)$, and $disk(C)$. The intersection of $disk(A)$ and $disk(B)$ lies in the interior of $disk(C)$. Without *a priori* knowledge that either node A or node B is the origin of this zone, we cannot compute a feasible representative point using standard Phase II methods.

point for use by the Steiner-zone heuristic.

Appendix G

LK-SOCP and CW-SOCP

In Chapters 2 - 4, we compared the performance of the Steiner-zone heuristic (SZH) to several heuristics, including YUAN+, LK-SOCP, and CW-SOCP. YUAN+, LK-SOCP, and CW-SOCP do not use Steiner zones. That is, they do not apply Phase I of SZH. Each method solves a TSP for the CETSP or a VRP for the CEVRP in Phase II. YUAN+ solves a TSP on the original n nodes to optimality using Concorde's exact TSP solver [1, 13]. LK-SOCP solves a TSP on the original n nodes using Concorde's implementation of the Lin-Kernighan TSP heuristic [1, 13]. CW-SOCP solves a VRP on the original nodes using Groër's implementation of the modified Clarke-Wright VRP heuristic [39]. All three methods solve Phase III to optimality for all routes found in Phase II. Concorde's implementation of the Lin-Kernighan heuristic (LK) is initialized by a random integer in [0, 32767]. The modified Clarke-Wright (mCW) heuristic uses a parameter λ which has values in (0, 2]. We think of YUAN+ as an optimal form of LK-SOCP since it is identical to LK-SOCP in every way except that Phase II is solved to optimality rather than approximately. We do not study YUAN+ specifically in this appendix because it achieves a similar accuracy to LK-SOCP but is much slower (see Chapter 2).

In Chapters 2 and 3, we found that for problems with high overlap ratios, LK-SOCP and CW-SOCP are generally faster than any SZH method and are more

accurate than any SZH method except those that apply Phase IV. For problems with low overlap ratio, LK-SOCP and CW-SOCP consistently produce poor results. In this appendix, we try to determine whether or not a problem's overlap ratio affects the performance of LK-SOCP and CW-SOCP. If LK-SOCP and CW-SOCP produce better tours than SZH for high overlap ratio problems, then we can consider a hybrid heuristic that applies LK-SOCP or CW-SOCP to high overlap ratio problems and a variant of SZH to problems with low and medium overlap ratios.

We computed two sets of 1001 solutions using the LK-SOCP heuristic for each CETSP problem using each norm (2D and 3D Euclidean, 2D and 3D Manhattan), with equal radius and arbitrary radius. For the first 1001 LK-SOCP runs, we used i to initialize the ith run of LK. The second 1001 tours were generated initializing LK with random integers in [0, 32767]. We also computed two sets of 1000 solutions using the CW-SOCP heuristic for each CEVRP problem, using each norm with equal radius and arbitrary radius. For the first 1000 CW-SOCP runs, we used $\lambda = \frac{i}{500}$ to initialize mCW for the ith run. The second 1000 solutions initialized mCW with a random value in (0, 2]. We report only the results produced by the first 1000 tours for each method since the results of the second 1000 were almost exactly the same as those of the first. We refer to the 1001 LK-SOCP tours as the LK1001 heuristic and the 1000 CW-SOCP solutions as the CW1000 heuristic.

G.1 CETSP

In Table G-1, we give the results for 48 CETSP problems with equal radius and 2D Euclidean norm. For the remainder of this section, all tables are formatted in the same manner. Column two displays the average length of the Phase II TSP tours found by LK1001 (LK found the optimal TSP tour at least once for all problems except $dsj1000$). All tour lengths are given to two decimal places. Column three shows the percentage difference between the worst and the best TSP tour lengths produced by LK. Column four gives the average length of the 1001 CETSP tours produced by LK1001. Column five shows the percentage difference between the longest and the shortest CETSP tours produced by LK1001. Columns six through eight display the results found by one run of LK-SOCP, SZ2, and SZ3. Recall that SZ2 is the standard variant of SZH, and SZ3 applies the Phase IV post-processor to the solution produced by Phase III for each of the four Phase I - Phase II - Phase III cycles in SZ2 (see Chapter 2).

When LK-SOCP is modified so that Phase II is solved to optimality, we call this method YUAN+ (see Chapter 2 and [73]). In columns nine and 10, we present the amount (as a percentage) that the solution produced by YUAN+ is better than the solutions produced by SZ2 and SZ3, respectively. In columns 11 and 12, we present the amount (as a percentage) by which the average CETSP tour produced by LK1001 is better than SZ2 and SZ3, respectively. In columns nine though 12, a negative percentage indicates that the SZH solution (either SZ2 or SZ3) is longer (poorer) than the YUAN+ or LK1001 solution. For example, the average LK1001

tour for low-overlap $kroD100$ is 0.34% longer than the tour produced by SZ2. The average LK1001 tour for low-overlap $rat195$ is 0.25% shorter than the SZ2 tour. Columns 13 and 14 indicate how many of the 1001 solutions are shorter than SZ2 and SZ3, respectively.

In Table G-1, we see that LK produces TSP tours that vary no more than 2% in length (column 3). However, the CETSP solutions produced from these TSP tours vary up to 47% (column 5 for $rd400$ is 47.29%). Comparing tour lengths of the four heuristics (columns 4, 6, 7, and 8), we see in columns 9 and 11 that for two low overlap ratio $TSPLIB$ problems, one medium overlap ratio $TSPLIB$ problem, and four high overlap ratio $TSPLIB$ problems, YUAN+ is 0.20% to 1.86% shorter than SZ2 on average. For two medium overlap ratio $TSPLIB$ problems and two high overlap ratio $TSPLIB$ problems, YUAN+ is 10% to 39% worse than SZ2 on average. Similarly, the average LK1001 solution is up to 1.76% shorter than SZ2's solution for two low overlap ratio problems, two medium overlap ratio problems, and four high overlap ratio problems. The average LK1001 solution is 10% to 31% longer than SZ2 for five of the $TSPLIB$ problems.

In columns 10 and 12, we see that YUAN+ and the average LK1001 tour are both longer than the SZ3 solution for 45 problems. In column 13, we see that, for nine of 27 $TSPLIB$ problems, only zero to 59 of the 1001 LK1001 solutions are shorter than the SZ2 solution. For five high overlap ratio problems and one medium overlap ratio problem, however, 959 to 1001 of the 1001 LK1001 solutions are shorter than the SZ2 solution. For 18 of the 48 problems, LK1001 produces better tours than SZ2 over 50% of the time (at least 561 tours). For 25 problems,

LK1001 produces zero to 86 tours better than SZ2's solution.

The results are different when we compare LK1001 to SZ3 in column 14. We see that in 39 problems, LK1001 produces zero solutions better than SZ3 and in two problems, it produces one solution that is better than the SZ3 solution. Recall that SZ3 applies Phase IV to each solution found in Phase III and is much slower but more accurate, in general, than LK-SOCP or SZ2. Only for the *rotatingDiamonds* problems, *concentricCircles*1, and *concentricCircles*2 are at least 5% of the 1001 LK1001 tours better than the SZ3 solution. SZ3 is more accurate than SZ2 and LK1001 (LK-SOCP) but slower. For the remainder of the appendix, we compare LK-1001 mostly with SZ2 and not SZ3.

The results given in Table G-1 indicate that LK-SOCP's performance is highly problem dependent. For many problems (10 of 14 low and medium overlap ratio $TSPLIB$ problems, 32 of 48 overall), the average length of the 1001 LK1001 solutions is longer than the SZ2 solutions, often well over 10% longer. For some problems (five of seven low overlap ratio $TSPLIB$ problems, 15 of 48 overall), 69% to 100% of the LK-SOCP solutions are shorter than the SZ2 solutions. It appears that the overlap ratio has a strong affect on the LK-SOCP heuristic's performance compared to SZ2.

The results in Tables G-2, G-3, and G-4 are very similar to those in Table G-1. For most problems, LK-SOCP either produces a slightly better solution than SZ2 on average or a substantially poorer solution. Over all four problem sets, over 50% of the LK1001 tours are better than the SZ2 solutions in 49 of 152 problems (32.24%). Over 50% of the tours are better than the SZ3 solutions in only four of 152 problems

(2.63%). LK1001 finds no solutions that are better than the SZ2 solutions for 43 of 152 problems (28.29%) and no solutions better than the SZ3 solutions for 128 of the 152 problems (84.21%).

Table G-2: LK1001, 3D Euclidean Norm, Equal Radius

(2): Average length of LK1001 TSP tours
(3): % difference between the best and worst of the TSP tours
(4): Average length of LK1001 CETSP tours
(5): % difference between the best and worst of the CETSP tours
(9): % that tour produced by YUAN+ is longer than the tour produced by SZ2
(10): % that tour produced by YUAN+ is longer than the tour produced by SZ3
(11): % that the average CETSP tour (column 4) is longer than the tour produced by SZ2
(12): % that the average CETSP tour (column 4) is longer than SZ3
(13): Number of LK1001 solutions that are longer than SZ2
(14): Number of LK1001 solutions that are longer than SZ3

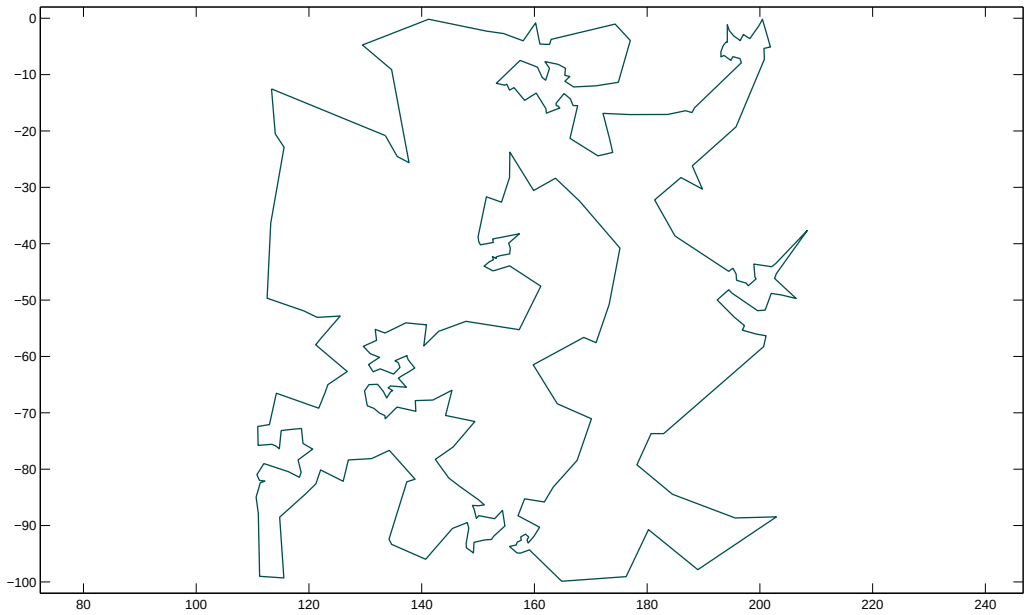
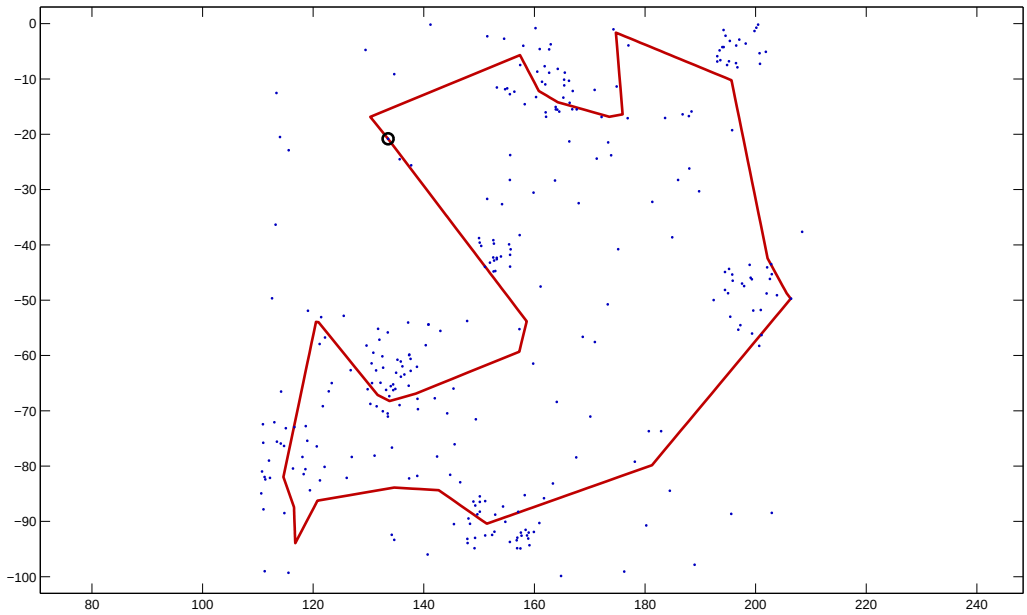
In Tables G-5 - G-8, we give the results for the same experiments as in Tables G-1 - G-4, except that we use arbitrary radius instead of equal radius. We have 14 arbitrary radius problems using each norm (2D Euclidean, 2D Manhattan, 3D Euclidean, 3D Manhattan).

The results for arbitrary radius problems show that LK1001 typically performs very poorly for these problems. For example, in column 13, we see that in 33 of the 47 problems for which we present results in Tables G-5 - G-8, none of the LK1001 tours are better than the SZ2 solution. In 41 of the 47 solutions, none of the LK1001 tours are better than the SZ3 solution. In only 11 of the 47 problems are more than 100 of the LK1001 tours better than the SZ2 solution. This suggests that LK-SOCP is not nearly as effective for solving arbitrary radius problems as it can be for problems with equal radius. We think that because the disk radii can vary so much for arbitrary radius problems, the best CETSP tour sequence may look nothing like the optimal TSP solution, as shown in Figure G.1. Applying Phase III to high-quality TSP tours for an arbitrary radius problem may not produce good CETSP solutions. Although this can also happen with equal radius problems, it seems much less likely to do so than for arbitrary radius problems.



(a) Optimal 300-node TSP tour



(b) Best known CETSP tour

Figure G.1: The optimal TSP solution and the best known solution for a 300-node CETSP with arbitrary radius.

G.2 CEVRP

We conducted the same experiments for the CEVRP as we did for the CETSP. We compare between the CW-SOCP, SZVRP2, and SZVRP4$_t$ heuristics (SZVRP2 and SZVRP4$_t$ are described in detail in Chapters 3 and 4). We use the modified Clarke-Wright (mCW) VRP heuristic. We do not have a CEVRP method analogous to YUAN+ for the CETSP (which solves Phase II to optimality) since currently, there is no exact VRP solver available that can solve VRPs much larger than 50 nodes. For the results in this section, we replace columns (9) and (10) from Section G.1 with columns that compare the CEVRP solution produced from the best mCW-produced VRP solution with the solution produced by SZVRP2. We included the *concentricCircles*, *bubbles*, *rotatingDiamonds*, and *chaoSingleDep* problems in experiments with 3D norms even though these problems are two-dimensional (the z-coordinate for every node in these problems is 0) to determine if the results were consistent with what we found in two dimensions. The optimal Phase III solution to these problems using 3D norms must leave every z-coordinate at 0 so that the solution remains unchanged when projected into two dimensions. This makes intuitive sense since the shortest path between coplanar points lies in the same plane.

In Tables G-9 to G-12, we give results for the CEVRP problems with equal radius using the 2D Euclidean, 3D Euclidean, 2D Manhattan, and 3D Manhattan norms. Column 3 in each table shows that the variation in the lengths of the VRP solutions found by mCW for a problem ranges from 0% (all 1000 VRP tours have the same length) to 139%, a much larger variation than produced by the LK heuristic

for CETSP problems. The difference is likely due to the Lin-Kernighan heuristic's accuracy and mCW's inaccuracy. Solutions produced by mCW are typically used as initial solutions for tour-improvement procedures rather than final, near-optimal solutions. The length of the CEVRP solutions that result from the VRP solutions (column 5) varies between 0% and 124%. This is also a much larger variation than the variation produced by LK1001.

In column 9 of the four tables, we see that the CEVRP solution produced by the best VRP solution is better than the SZVRP2 solution in 91 of 192 problems (up to 28%). For 101 of the 192 problems, the CEVRP solution produced by the best VRP solution is worse than the SZVRP2 solution (up to 26%). In column 10, we see that the CEVRP solution produced from the best VRP solution is better than the SZVRP4$_t$ solution in only 30 of 192 problems. Columns 11 and 12 reveal that the average length of the 1000 CW1000 solutions is better than SZVRP2 in 65 of 192 problems and better than SZVRP4$_t$ in only 16 of 192 problems.

Columns 13 and 14 of the four tables show that CW-SOCP performs very well on medium and high overlap ratio problems. For 38 of 56 medium and high overlap ratio $TSPLIB$ problems, more than 50% of the CW1000 solutions are better than SZVRP2's solutions. For 26 of the 28 high overlap ratio $TSPLIB$ problems, at least one of the 1000 CW1000 solutions is better than SZVRP4$_t$'s solution, and in 15 of the 28 problems, more than 40% of the CW1000 solutions are better than SZVRP4$_t$'s solution. For low overlap ratio $TSPLIB$ problems, CW-SOCP performs very poorly. We see that for 25 of 28 low overlap ratio $TSPLIB$ problems, none of the CW1000 solutions are better than SZVRP2's solution.

Over all 192 problems in the four tables, more than 50% of the 1000 CW1000 solutions are better SZVRP2's solution in 75 of the problems (39.06%) and are better than SZVRP4$_t$'s solution in 21 of the problems (10.94%). CW1000 produces no solutions better than SZVRP2's solution in 65 of the 192 problems (33.85%) and no solutions better than SZVRP4$_t$'s solution in 122 of the 192 problems (63.54%). The percentage of problems on which CW1000 finds no solutions better than SZVRP2 (33.85%) is larger than the percentage of problems for which LK1001 finds no solutions better than SZ2 (28.29%). However, the percentage of problems on which over 50% of the CW1000 tours are better than SZVRP2 (39.06%)) is larger than the percentage of problems on which over 50% of the LK1001 tours are better than SZ2 (32.24%). CW-SOCP seems to be effective on medium overlap ratio problems and highly effective for high overlap ratio problems, and completely ineffective for low overlap ratio problems. It is interesting that CW-SOCP does so well for so many problems even though using mCW with SZH as a Phase II VRP solver does so poorly (see the results for SZVRP1 and its variants in Chapters 3 and 4).

Table G-9: CW1000, 2D Euclidean Norm, Equal Radius

(2): Average length of CW1000 VRP solutions
(3): % difference between the best and worst of the VRP solutions
(4): Average length of 1001 CEVRP solutions
(5): % difference between the best and worst of the CEVRP solutions
(9): % that CEVRP solution produced by the best mCW solution is longer than the SZVRP2 solution
(10): % that CEVRP solution produced by the best mCW solution is longer than the SZVRP4$_t$ solution
(11): % that the average CEVRP solution (column 4) is longer than the SZVRP2 solution
(12): % that the average CEVRP solution (column 4) is longer than the SZVRP4$_t$ solution
(13): Number of CW1000 solutions that are longer than the SZVRP2 solution
(14): Number of CW1000 solutions that are longer than the SZVRP4$_t$ solution

Table G-11: CW1000, 2D Manhattan Norm, Equal Radius

(2): Average length of CW1000 VRP solutions
(3): % difference between the best and worst of the VRP solutions
(4): Average length of 1001 CEVRP solutions
(5): % difference between the best and worst of the CEVRP solutions
(9): % that CEVRP solution produced by the best mCW solution is longer than the SZVRP2 solution
(10): % that CEVRP solution produced by the best mCW solution is longer than the SZVRP4$_t$ solution
(11): % that the average CEVRP solution (column 4) is longer than the SZVRP2 solution
(12): % that the average CEVRP solution (column 4) is longer than the SZVRP4$_t$ solution
(13): Number of CW1000 solutions that are longer than the SZVRP2 solution
(14): Number of CW1000 solutions that are longer than the SZVRP4$_t$ solution

In Tables G-13 - G-16, we give the results using arbitrary radius. We have 14 arbitrary radius CEVRP problems using each norm.

The values in columns 3 and 5 are similar to those for equal radius problems. There is a large variation in the VRP routes produced by mCW and in the CEVRP solutions produced from the VRP routes. Columns 9 through 14 show that CW1000 does not perform nearly as well on arbitrary radius CEVRP problems as it does on equal radius problems. In column 9 of the four tables, we see that the CEVRP solutions produced from the best VRP tour is shorter than SZVRP2's solutions in four of the 56 problems. Column 10 of the four tables shows that the CEVRP solution produced from the best VRP tour is longer than the SZVRP4$_t$ solution in every problem. In columns 11 and 12, we see that the average of the 1000 CEVRP solutions produced by CW1000 is longer (up to 38%) than both the SZVRP2 and SZVRP4$_t$ solutions in all 56 problems. Columns 13 and 14 show that in only seven of the 56 problems are any of the CW1000 solutions better than SZVRP2's solutions, and in none of the problems are any CW1000 solutions better than the SZVRP4$_t$ solutions.

These results are similar to the results on arbitrary radius problems for LK1001. CW1000 does not perform nearly as well for arbitrary radius problems as it does for medium and high overlap ratio equal radius problems.

Table G-13: CW1000, 2D Euclidean Norm, Arbitrary Radius

(2): Average length of CW1000 VRP solutions
(3): % difference between the best and worst of the VRP solutions
(4): Average length of 1000 CEVRP solutions
(5): % difference between the best and worst of the CEVRP solutions
(9): % that CEVRP solution produced by the best mCW solution is longer than the SZVRP2 solution
(10): % that CEVRP solution produced by the best mCW solution is longer than the SZVRP4$_t$ solution
(11): % that the average CEVRP solution (column 4) is longer than the SZVRP2 solution
(12): % that the average CEVRP solution (column 4) is longer than the SZVRP4$_t$ solution
(13): Number of CW1000 solutions that are longer than the SZVRP2 solution
(14): Number of CW1000 solutions that are longer than the SZVRP4$_t$ solution

G.3 Conclusions

In Chapters 2 - 4, we saw that methods that do not use Steiner zones (LK-SOCP, YUAN+, CW-SOCP) were extremely fast and consistently outperformed SZH (without Phase IV) on certain types of problems. When averaged over all problem types, LK-SOCP, YUAN+, and CW-SOCP did not perform nearly as well as SZH. In this appendix, we tested the performance of the three methods to learn more about their performance. We observed the following. (1) Overlap ratio strongly affects the performance of methods that do not use Steiner zones. LK-SOCP, YUAN+, and CW-SOCP almost never do well on problems with low overlap ratio. For high overlap ratio problems, for many problems (especially for CW-SOCP) they find better solutions on average than SZH. (2) On a large percentage of problems, LK-SOCP, YUAN+, and CW-SOCP either never produce better solutions than SZH or almost always produce better than SZH. This happens across all overlap ratios, indicating that something else other than overlap ratio, probably the layout of the nodes, affects their performance. (3) LK-SOCP, YUAN+, and CW-SOCP do not perform well on problems with arbitrary radius. We think it is intuitive that the optimal CETSP or CEVRP node sequence is often substantially different from the optimal TSP or VRP node sequence - much more so than when the radius is equal for all disks.

The computational speed of LK-SOCP and CW-SOCP, along with their accuracy on equal radius problems with medium and high overlap ratio, suggest that a hybrid SZH+LK-SOCP or SZH+CW-SOCP heuristic would be very competitive.

For problems with medium or high overlap ratio and equal radius, LK-SOCP or CW-SOCP could be applied in addition to SZH, improving the accuracy of the solution with only a small increase in computation time.

Appendix H

Pseudocode: SDTOP HotnCold Algorithm

```
M: set of nodes moved in the candidate solution
META_current: current meta-route
currScore: current objective function value
newVal = currScore
Obtain arrival times for all visited nodes in the potential move.
Merge-sort all nodes that are visited in the candidate solution into a new meta-route,
META_potential.
for all visited nodes do //Determine the sets of hot nodes and cold nodes
  if node i ∈ M or i is in a route containing a node from M and i succeeds that node
  then
    Put i in HOT
  else
    Put i in COLD
  end if
end for
for all nodes i in HOT do //hot/cold comparisons
  for all nodes j in COLD do
    if i before j in META_current but j before i in META_potential then
      newVal = newVal + p_ji − p_ij
    else if i after j in META_current but i before j in META_potential then
      newVal = newVal + p_ij − p_ji
    end if
  end for
end for
for all nodes i in HOT do //hot/hot comparisons
  for all nodes j after i in HOT do
    if i before j in META_current but j before i in META_potential then
      newVal = newVal + p_ji − p_ij
    else if i after j in META_current but i before j in META_potential then
      newVal = newVal + p_ij − p_ji
    end if
  end for
end for
return newVal
```

Algorithm 3: Objective function calculation for a candidate move using the HotnCold algorithm.

Appendix K

Alternative SDTOP Formulations

In this appendix we present two alternative formulations for the SDTOP. The first recognizes a simultaneous arrival between nodes i and j and counts neither p_{ij} nor p_{ji} in the objective function value. The other explicitly forbids simultaneous arrivals from occurring. Both models include an additional $4 * N(N-1)$ variables to the formulation given in Section 5.4.2. We consider heterogeneous fleets in both models.

<u>Constants</u>:

- N -number of possible nodes, excluding the depot (node 0)
- K -total number of vehicles available for use
- k_{min} - minimum number of vehicles to be used in the solution
- k_{max} - maximum number of vehicles to be used in the solution
- P - profit matrix
- p_{ij} - profit received for visiting i before j
- q_i - demand at node i
- 0_k - starting depot for the kth vehicle, which may be different for each vehicle. It is only really necessary for the constants related to the depot, but we use it for consistency everywhere.
- $\bar{0}_k$ - destination depot for the kth vehicle, which may be different than the

starting depot, and may be different for each vehicle. It is only really necessary for the constants related to the depot, but we use it for consistency everywhere.

- Q_k - maximum capacity for vehicle k -loses the subscript in the simple model formulation when vehicle fleet is homogeneous
- s_i - service time required at node i; $s_0 = 0$ by definition
- T - time/distance matrix (any distance norm is allowed)
- t_{ij} - travel time/distance between i and j
- $\bar{t}_{i\bar{0}_{mDiff}}$ -for node i, the absolute value of $\max_k(t_{i\bar{0}_k})$ - $\min_k(t_{i\bar{0}_k})$
- T_k - maximum travel time/distance for vehicle k -loses the subscript in the simple model formulation when vehicle fleet is homogeneous
- T_{max} - largest travel time/distance of all k vehicles, i.e. $\max_k(T_k)$
- Q_{max} - $\max(Q_k)$, largest capacity of all k vehicles; not used in the formulations
- ϵ - cutoff value for simultaneous arrivals; if two arrival times are less than ϵ units apart, they are considered simultaneous
- LB_{a_i} - lower time window for arriving at node i if node i is actually visited.
- UB_{a_i} - upper time window for arriving at node i if node i is actually visited.

<u>Variables</u>: $(i \neq j)$; $i > 0$ and $j > 0$ unless otherwise specified.

- $x_{ijk} = 1$ if vehicle k travels from node i to node j; 0 o.w.
- $y_{ik} = 1$ if node i, for $i \geq 0$, is visited by vehicle k; 0 o.w.
- $u_k = 1$ if vehicle k is used in the solution; 0 o.w.
- $w_i = 1$ if node i is visited in general; 0 o.w.
- a_i is the time that node i, for $i \geq 0$, is visited; if node i not visited, a_i is forced

to any number in [0, $N\epsilon$]

- $\delta_{ij} = a_j - a_i$; difference in arrival times
- $\Delta_{ij} = |\delta_{ij}|$ is the magnitude of the difference in arrival times for i and j
- v_{ij} is an indicator variable used to calculate Δ_{ij}
- $z_{ij} = 1$ if i's arrival time is before or simultaneous with j's time
- $\alpha_{ij} = 1$ if both i and j are visited; 0 o.w.
- $\beta_{ij} = 1$ if both i and j are visited and i's arrival time is before or simultaneous with j; 0 o.w.
- $\gamma_{ij} = 1$ if $\Delta_{ij} \leq \epsilon$, 0 o.w., for the generalized P case where simultaneous arrivals are allowed. If they are explicitly forbidden and P is generalized then it is 1 if both i and j are visited and i's arrival time strictly precedes that of j; 0 otherwise.

We do not assume the absence of simultaneous arrivals. SDTOP$_{general}$ adds p_{ij} to the objective function if i is visited before or simultaneous to j. For those pairs of arrivals, i and j, that are simultaneous, it subtracts both p_{ij} and p_{ji} from the objective function. Although SDTOP$_{general}$ is valid for an inverse symmetric P, SDTOP$_{simp}$ is preferable because of its relative simplicity. For a heterogeneous fleet and an inverse symmetric P, SDTOP$_{simp}$ may be modified by replacing the relevant constraints in SDTOP$_{simp}$ with the heterogeneous-fleet constraints in SDTOP$_{general}$.

$$\alpha_{ij},\ \beta_{ij},\ w_i,\ x_{ijk},\ y_{ik},\ z_{ij} \in \{0, 1\} \qquad \forall\ i, j, k$$

The objective function (K1) sums the pairwise profits, p_{ij}, for every pair of nodes that is visited such that i is visited before or simultaneous to j and subtracts out p_{ij} and p_{ji} erroneously added when i and j are visited simultaneously. Constraints (K2) and (K3) require that the depot be visited at time 0 by all vehicles, whether or not they actually visit any nodes. Since w_i is binary, constraint (K4) requires that every node is visited, if at all, by exactly one vehicle. w_i is a bookkeeping variable and only included to help with readability. (K5) guarantees that capacity feasibility is maintained.

Constraints (K6) to (K9) are the flow balance constraints requiring node i, if it is visited, to have exactly one predecessor and one successor. Without (K2) and (K3), a_0 can be greater than 0 (maximizing the objective function might cause a_0 to be assigned a value that allows the objective function for a particular meta-routes to be given a larger value than is correct). The arrival time equations discussed below (constraints (K30) and (K31)) then compute incorrect arrival times. With constraints (K2) and (K3) included, every vehicle is forced to visit its depot at

time 0, whether or not it visits other nodes, and the arrival time equations behave correctly. Because every vehicle is forced to visit its depot, we must modify the flow constraints in and out of the depot by adding the $-(1 - u_k)$ term to constraints (K6) and (K8). If vehicle k is not used in a non-trivial route, these two constraints are automatically satisfied. If vehicle k is used ($u_k = 1$) then vehicle k's initial depot must have exactly one successor and its ending depot must have exactly one predecessor.

Constraints (K10) to (K25) are specific to the SDTOP. (K10) is a book-keeping constraint storing the difference in arrival times between nodes i and j and is included only for easier reading. Constraints (K11) to (K14) compute the magnitude of the pairwise difference in arrival times using a disjunctive approach. In a linear programming minimization, the usual method of computing the absolute value, $AbsX$, of variable x requires that $AbsX$ appear in the objective function so that the objective function forces $AbsX \geq x$ and $AbsX \geq -x$ to hold at equality. This is not the case with the SDTOP, so instead, we use these four constraints.

Consider an example. Let i and j both be visited, i after j. Without loss of generality, let $a_i = 21$ and $a_j = 10$. Then $\delta_{ij} < 0$ and in fact equals -11. If $\Delta_{ij} < |\delta_{ij}|$, then constraint (K13) is violated. If $\Delta_{ij} > |\delta_{ij}|$, constraints (K13) and (K14) hold, but (K11) and (K12) are violated (constraint (K12) forces v_{ij} to 1, and constraint (K11) falsely implies that a positive minus a negative is a negative). If $\Delta_{ij} = |\delta_{ij}|$, then v_{ij} is forced to 1 and constraint (K11) holds at equality.

If i and j are both visited, i before j, similar analysis shows that these constraints again correctly calculate the absolute value of δ_{ij}. If i and j are visited at

precisely the same time, Δ_{ij} is forced to 0, but v_{ij} is not forced to any value. This does not affect the model's correctness because v_{ij} is not linked to the objective function and Δ_{ij} is correctly computed.

Constraints (K15) and (K16) force z_{ij} to 1 if j's arrival time follow's i, even if j actually was not visited. For example, if δ_{ij} is positive then constraint (K15) forces z_{ij} to 1, and constraint(K16) forces z_{ji} to 0 (since δ_{ji} is negative). If $\delta_{ij} = 0$, then both constraints hold without forcing z_{ij} to either 0 or 1. Since z_{ij} is indirectly linked to the objective function variables, this can allow the erroneous case where both p_{ij} and p_{ji} are counted. There are two possible cases where δ_{ij} can equal 0. One is that i and j are both visited simultaneously (within ϵ of each other where ϵ can take meaningful values anywhere from near zero to much larger time frames). The second way that δ_{ij} can equal 0 is if both i and j are not visited and we omit constraint (K33). We discuss this in detail below.

If $\Delta_{ij} < \epsilon$, i and j are considered to be simultaneous arrivals. Constraint (K17) forces both z_{ij} and z_{ji} to 1 in this situation. If arrival times are simultaneous within ϵ, z_{ij} and z_{ji} are forced to 1. Because i and j are both visited (α_{ij} and α_{ji} will equal 1) and z_{ij} and z_{ji} are both 1, β_{ij} and β_{ji} will both equal 1 and p_{ij} and p_{ji} will both be counted in the objective function. If P has the inverse property, this is okay since p_{ij} and p_{ji} cancel each other out. However, if P is generalized, $p_{ij} + p_{ji}$ may equal anything, so we modify the objective function (K1) and add additional constraints, (K22) through (K25), described below.

In (K18) and (K19), if neither i nor j is visited, then constraint (K18) forces α_{ij} to 0 so that $-(0 + 0) \leq 0$. If exactly one of i and j is visited then (K18) again

forces α_{ij} to 0 so that $-(1+0) \leq 0$ or $-(0+1) \leq 0$. If both i and j are visited, then (K19) forces α_{ij} to 1 so that $2 \leq 1 + \alpha_{ij}$ holds. Thus, α_{ij} is forced to 1 if and only if both i and j are visited, 0 otherwise.

(K20) and (K21) tie all the additional binary variables together. If both α_{ij} and $z_{ij} = 0$, then constraint (K20) forces β_{ij} to 0 so that $-(0+0) \leq 0$. If either $\alpha_{ij} = 1$ or $z_{ij} = 1$, but not both, then (K20) again forces β_{ij} to 0 so that $-(1+0) \leq 0$ or $-(0+1) \leq 0$. If $\alpha_{ij} = z_{ij} = 1$, then (K21) forces β_{ij} to 1 so that $2 \leq 1 + \beta_{ij}$ holds. Thus, β_{ij} is 1 if and only if i and j are both visited and i's arrival precedes or is simultaneous to j's. Otherwise, $\beta_{ij} = 0$.

We desire γ_{ij} to be 1 if and only if $|a_i - a_j| < \epsilon$. This is accomplished with constraints (K22) and (K23) which force γ_{ij} to 1 when Δ_{ij} is less than ϵ (effectively 0), 0 otherwise.

Now, assume that we do not include the $N\epsilon$ term in constraint (K33), and we do not include constraints (K24), and (K25) in the model. Let i and j be two unvisited nodes. a_i and a_j are forced to 0 by constraint (K33) so that $\Delta_{ij} = \Delta_{ji} = 0$; this is a simultaneous arrival. β_{ij} and β_{ji} both equal 0 since i and j are not visited, but γ_{ij} and γ_{ji} are forced to 1 which invalidates the model.

Next, add the $N\epsilon$ term back to constraint (K33). Now, every unvisited node can be given an arrival time between 0 and $N\epsilon$ at least ϵ units apart. We note that if two nodes are less than $N\epsilon$ units apart, any route that visits the two nodes consecutively automatically contains a simultaneous arrival.

However, there is no mechanism to force the arrival times to be at least ϵ units apart. Let P be inverse symmetric. An inverse symmetric P should automatically

imply that the model in Section B.1 is solved (since $p_{ij} + p_{ji} = 0$, simultaneous arrivals are not a concern) but is certainly not required. Let i and j again be unvisited nodes. Their arrival times are both forced to less than $N\epsilon$, say 2ϵ and 3ϵ where $N >= 3$. Δ_{ij} and Δ_{ij} are therefore ϵ. If $p_{ij} < 0$ ($p_{ji} < 0$), constraints (K22) and (K23) do not force γ_{ij} and γ_{ji} to 0. The objective function will then drive γ_{ij} but not γ_{ji} (γ_{ji} but not γ_{ij}) to 1 and increase in value. This is erroneous.

Now, add constraints (K24) and (K25) back to the model. Continuing our example, i and j are both unvisited (so that $w_i = w_j = 0$) and $\Delta_{ij} = \Delta_{ji} = \epsilon$. Here, if the objective function pushes either γ_{ij} or γ_{ji} to 1, (K24) and (K25) both evaluate to $1 \leq 0$ which is infeasible. Thus, the final loophole is closed and simultaneous arrivals are correctly handled. The objective function will count only the proper profits since y_{ik} and w_i, then z_{ij} and α_{ij}, and finally β_{ij}, will all be pushed towards 1 while γ_{ij} is pushed to 0.

u_k is a binary variable equal to 1 if and only if vehicle k visits any node other than the depot, 0 otherwise. That is, if vehicle k visits no other node than the depot, constraint (K26) forces u_k to 0. If vehicle k visits any node other than the depot, constraint (K27) forces u_i to 1. In general, an optimal $k+1$-vehicle solution is not necessarily better than an optimal k-vehicle solution, as previously illustrated in Figure 5.1. Constraints (K28) and (K29) dictate how many vehicles are used in the solution with $k_{min} = 1$ and $k_{max} = K$ being a typical choice. These two constraints do not specify which of the K vehicles must be chosen.

Constraints (K30) and (K31) fix the arrival times for all nodes, whether or not they are visited. To understand this constraint, consider an example with a

homogeneous fleet. Since $T_{max} = T$, the $y_{jk}(T_{max} - T)$ term drops out and we are left with:

$$a_i + x_{ijk}(s_i + t_{ij} + T) \leq T + a_j \quad \forall\ k;\ i \geq 0,\ j \geq 1$$

$$-a_i + x_{ijk}(T - (s_i + t_{ij})) \leq T - a_j \quad \forall\ k;\ i \geq 0,\ j \geq 1$$

$$\forall\ k;\ i \geq 0,\ j \geq 1 \text{ for both constraints}$$

If edge ij is not included in vehicle k's tour, then we do not want its associated arrival time constraints to restrict i and j's arrival times in any way. This holds since $a_i \leq T + a_j$ and $a_i \geq a_j - T$. If edge ij is included in vehicle k's tour, then the T's cancel out and we have that $a_i + (s_i + t_{ij}) \leq a_j$ and $a_i + (s_i + t_{ij}) \geq a_j$. That is, $a_j = a_i + (s_i + t_{ij})$.

When the fleet is heterogeneous, the logic remains the same, but the details are messier. Without loss of generality, assume we have a two-vehicle fleet ($K = 2$) where $T_1 = 100$ and $T_2 = 12$ (any $T_1 > T_2$ will do). T_{max} must be 100, $T_{max} - T_1 = 0$ and $T_{max} - T_2 = 88$. $t_{i\bar{0}_1} = 3$, $t_{i\bar{0}_2} = 5$, and $\bar{t}_{i\bar{0}_{mDiff}} = 2$. Assume we model these constraints as:

$$a_i + x_{ijk}(T_k + (s_i + t_{ij})) \leq\ T_k + a_j$$

$$-a_i + x_{ijk}(T_k - (s_i + t_{ij})) \leq\ T_k - a_j$$

$$\forall\ k;\ i \geq 0,\ j \geq 1 \text{ for both constraints}$$

If edge ij is not included in vehicle 1's tour, we must satisfy $a_i \leq 100 + a_j$ and $a_i \geq a_j - 100$. This means that $a_i - 100 \leq a_j \leq a_i + 100$ which is valid since neither i nor j's arrival time is restricted more than their bounds. If edge ij is not

included in vehicle 2's tour, we must satisfy $a_i \leq 12 + a_j$ and $a_i \geq a_j - 12$. That is, $a_i - 12 \leq a_j \leq a_i + 12$. This is a problem since the constraint should not restrict either a_i or a_j. Therefore, the T in the righthand-side of each constraint must be replaced by T_{max}. We now have:

$$a_i + x_{ijk}(T_k + (s_i + t_{ij})) \leq \ T_{max} + a_j$$

$$-a_i + x_{ijk}(T_k - (s_i + t_{ij})) \leq \ T_{max} - a_j$$

$$\forall\ k;\ i \geq 0,\ j \geq 1 \text{ for both constraints}$$

Continuing our two-vehicle example, without loss of generality let $s_i + t_{ij} = 4$ (any number $< T_2$ will do) and let i be the depot ($a_i = 0$). The constraints would be:

$$0 + 104x_{ij1} \leq \ 100 + a_j$$

$$-0 + 96x_{ij1} \leq \ 100 - a_j$$

$$0 + 16x_{ij2} \leq \ 100 + a_j$$

$$-0 + 8x_{ij2} \leq \ 100 - a_j$$

Although $T_2 = 12$, edge ij could be included in vehicle 2's route for any $a_j \leq 92$ and is not forced to any particular value. Even in tandem with constraint (K32), a_j can take any value such that $0 + s_j + t_{0_2 j} + t_{j\bar{0}_2} \leq 12$. The constraints are incorrect since a_j should be forced to exactly one value if included in vehicle 2's route.

Next, assume that we change the T_k term on the lefthand-side to T_{max}. We

have:

$$a_i + x_{ijk}(T_{max} + (s_i + t_{ij})) \leq \ T_{max} + a_j$$

$$-a_i + x_{ijk}(T_{max} - (s_i + t_{ij})) \leq \ T_{max} - a_j$$

$$\forall\ k;\ i \geq 0,\ j \geq 1 \text{ for both constraints}$$

Continuing our example, for vehicle 2, these constraints would look like:

$$a_i + 104x_{ij2} \leq \ 100 + a_j$$

$$-a_i + 96x_{ij2} \leq \ 100 - a_j$$

Again, let i be the depot ($a_i = 0$) and $s_0 + t_{0_2 j} = 4$ ($s_0 = 0$ by definition). We now have:

$$104x_{ij2} \leq \ 100 + a_j$$

$$96x_{ij2} \leq \ 100 - a_j$$

Therefore, $a_j \leq 4$. In tandem with constraint (K32), a_j can take any value such that $0 + 4 + t_{j\bar{0}_2} \leq 12$. The constraints are still incorrect because if j is visited in route k, the arrival time constraints pertaining to i, j, and route k should force a_j to exactly one value rather than an interval.

Now, replace the T_{max} on the lefthand-side with T_k, as we had it, and add in the $y_{jk}(T_{max} - T_k)$ term. We now have constraints (K30) and (K31) as they appear

in SDTOP$_{general}$. For our two-vehicle example, the constraints are:

$$a_i + 104x_{ij1} + 0y_{j1} \leq \ 100 + a_j$$

$$-a_i + 96x_{ij1} + 0y_{j1} \leq \ 100 - a_j$$

$$a_i + 16x_{ij2} + 88y_{j2} \leq \ 100 + a_j$$

$$-a_i + 8x_{ij2} + 88y_{j2} \leq \ 100 - a_j$$

If edge ij is not included in either tour, these constraints do not restrict the values of either a_i or a_j. If edge ij is included in vehicle 1's tour ($x_{ij1} = y_{j1} = 1$ and $x_{ij2} = y_{j2} = 0$), a_j is forced to equal exactly $a_i + 4$, and vehicle 2's constraints do not restrict a_j. If edge ij is included in vehicle 2's tour ($x_{ij2} = y_{j2} = 1$ and $x_{ij1} = y_{j1} = 0$), a_j is also forced to equal exactly $a_i + 4$, and vehicle 1's constraints do not restrict a_j.

Constraint (K32) requires that the arrival time for any node is early enough so that its vehicle can feasibly reach its depot. Note that when $i = 0$, t_{ij} is actually $t_{0_k j}$. Consider an example, letting the righthand side of (K32) equal T_k . Once again using our two-vehicle example from above, let $y_{i1} = 0$, $y_{i2} = 1$, and $a_i = 7$. Vehicle 2 visits node i at time 7. The constraints are:

$$7 + (3 - 100) \leq 100$$

$$7 + (5 - 100) \leq 12$$

Both constraints are valid which is as it should be. However, if vehicle 1 infeasibly visits node i at time 103, the constraints do not work. $y_{i1} = 1$, $y_{i2} = 0$, and $a_i = 103$.

The constraints are:

$$103 + (3 - 100) \leq 100$$

$$103 + (5 - 100) \leq 12$$

which incorrectly is feasible for both constraints. Now, let the righthand side = 0 and remove the y_{ik} term. It is easily verified that the above situations are handled correctly. Assume, vehicle 2 visits node i at time 7. $y_{i1} = 0$, $y_{i2} = 1$, and $a_i = 7$. The constraints are:

$$7 + (3 - 100) \leq 0$$

$$7 + (5 - 100) \leq 0$$

which correctly says this is feasible. However, if vehicle 1 visits node i at time 96, the constraints do not work. $y_{i1} = 1$, $y_{i2} = 0$, and $a_i = 96$. The constraints are:

$$96 + (3 - 100) \leq 0$$

$$96 + (5 - 100) \leq 0$$

which is infeasible. These constraints are invalid because vehicle 1 would return to its depot at time 99 which is feasible.

Now, add to $-y_{ik}(T_{max} - T_k)$ the righthand side and recall that $(T_{max} - T_1 = 0$ and $T_{max} - T_1 = 88$. It is easily verified that the first three scenarios we have described are handled correctly. However, if vehicle 1 visits node i at time 96, the constraints still do not work. $y_{i1} = 1$, $y_{i2} = 0$, and $a_i = 96$. The constraints are:

$$96 + (3 - 100) \leq -1 \cdot 0$$

$$96 + (5 - 100) \leq 0 \cdot 88$$

which is infeasible although vehicle 1 can feasibly visit node i at time 96.

Next, let the righthand side be $(1 - y_{ik})\bar{t}_{i\bar{0}_{mDiff}}$. Recall that $t_{i\bar{0}_1} = 3$, and $t_{i\bar{0}_2} = 5$. Therefore, $t_{i\bar{0}_{max}} = 5$, $t_{i\bar{0}_{min}} = 3$, and $\bar{t}_{i\bar{0}_{mDiff}} = 2$. If vehicle 1 visits node i at time 96, the constraints are:

$$96 + (3 - 100) \leq (1 - 1) \cdot 2$$

$$96 + (5 - 100) \leq (1 - 0) \cdot 2$$

which correctly allows the values given. If $a_i = 97$, which is the latest that vehicle 1 can feasibly visit node i, the constraints still work. For $a_i > 97$, the constraints correctly forbid this infeasibility. It is easily verified that this form of the constraint works for the other scenarios described above.

There is one remaining scenario to consider for a visited node i. Let vehicle 2 visit i at time 10, which should be recognized as infeasible $(10 + 5 > 12)$. $y_{i1} = 0$, $y_{i2} = 1$, and $a_i = 10$. The constraints are:

$$10 + (3 - 100) \leq (1 - 0) \cdot 2$$

$$10 + (5 - 100) \leq (1 - 1) \cdot 2$$

which incorrectly allows i to be visited at an infeasible time.

Finally, let the righthand side be $(1 - y_{ik})\bar{t}_{i\bar{0}_{mDiff}} - y_{ik}(T_{max} - T_k)$. Combining terms and moving the y_{ik} terms to the lefthand side, we obtain constraint (K32) as it appears in SDTOP$_{general}$. For the scenario given above the constraints are:

$$10 + (3 - 100) \leq (1 - 0) \cdot 2 - (0 \cdot 100)$$

$$10 + (5 - 100) \leq (1 - 1) \cdot 2 - (1 \cdot 88)$$

which correctly identifies $-85 < -88$ as infeasible. It can easily be verified that all the scenarios above are handled correctly by constraint (K32).

However, constraint (K32), alone, does not suffice when i is unvisited. In this case every constraint Constraint(K33), in conjunction with (K24) and (K25)), forces the arrival time of unvisited nodes into the interval $[0, N\epsilon]$. Without (K33), (K32) could unnecessarily restrict a_i as shown previously.

Groër et al., [40], have pointed out both that (K30) eliminates subtours and that (K31) could be dropped if we wanted to allow vehicles to wait at node i. However, although redundant, adding some of the standard subtour elimination constraints in (K34), with cardinality no larger than $n/2$, helps achieve faster solution times since they are tighter than (K31).

K.2 Explicitly Excluding Simultaneous Arrivals

The third model explicitly forbids simultaneous arrivals. Note that in the second model, $\beta_{ij} + \beta_{ji} = 2$ if and only if $a_i = a_j$ and i and j are visited. This is due to the maximization pushing z_{ij} and z_{ji} both to 1. To forbid simultaneous arrivals, we modify $\text{SDTOP}_{general}$ to include a new objective (K35) and additional constraints (K36) through (K39), and we remove constraints (K22) through (K25). In this formulation, called $\text{SDTOP}_{noSimul}$ γ_{ij} are the objective function variables. The first two constraints force γ_{ij} to 0 if neither i nor j is visited or if both are visited such that $a_{ij} = a_{ji}$. The last two constraints force the correct γ (γ_{ij} or γ_{ji}) to 1. Without these two constraints, if $\beta_{ij} = 1$ and $p_{ij} < 0$, γ_{ij} could still equal 0 to avoid lowering the objective function. When an optimal solution to the first model

has simultaneous arrivals, that solution will not be optimal to this version.

$$\text{Maximize} \qquad \sum_{i=1}^{N}\sum_{j=1}^{N} p_{ij}\gamma_{ij} \tag{K35}$$

$$-(\beta_{ij} + \beta_{ji}) \leq -\gamma_{ij} \qquad \forall\ i \geq 1,\ j \geq 1 \tag{K36}$$

$$\beta_{ij} + \beta_{ji} \leq 2 - \gamma_{ij} \qquad \forall\ i \geq 1,\ j \geq 1 \tag{K37}$$

$$\frac{1}{2}\gamma_{ij} - \beta_{ij} \leq 0 \qquad \forall\ i \geq 1,\ j \geq 1 \tag{K38}$$

$$\beta_{ij} - \gamma_{ij} \leq 0 \qquad \forall\ i \geq 1,\ j \geq 1 \tag{K39}$$

K.3 Using the Minimum Number of Variables

Both δ_{ij} and w_i are book-keeping variables included to make the formulations easier to read. They are unnecessary for model correctness. If we leave δ_{ij} out, constraint K10 is removed and all occurrences of δ_{ij} are replaced by $(a_j - a_i)$. To remove w_i, replace constraint (K4) with (K40), and replace all other occurrences of w_i with $\sum_{k=1}^{K} y_{ik}$. In preliminary experiments, we found that the lower bound increases somewhat faster when we include δ_{ij} and w_i in any of the formulations.

$$\sum_{k=1}^{K} y_{ik} \leq 1 \qquad \forall\ i \geq 1 \tag{K40}$$

K.4 Extensions

We can add in constraints to force a_i to be visited within some time window, if it is actually visited, otherwise 0. This is done using constraints (K41) and (K42).

$$a_i - (1 - w_i)T_{Max} \leq UB_{a_i} \qquad \forall\ i \geq 1 \tag{K41}$$

$$a_i + (1 - w_i)T_{Max} \geq LB_{a_i} \qquad \forall\ i \geq 1 \tag{K42}$$

$0 \leq a_i \leq N\epsilon$ when node i is not visited, so the w_i term can be dropped and constraint (K41) becomes (K43). This assumes that $UB_{a_i} > N\epsilon$.

$$a_i \leq UB_{a_i} \qquad \forall\ i \geq 1 \tag{K43}$$

In some situations, it may make sense that no two nodes can be visited within a certain period ($\gg 0$) of each other. That is, we want no simultaneous arrivals and the ϵ used to indicate one is $\gg 0$. In this situation, both SDTOP$_{general}$ and SDTOP$_{noSimul}$ can be used. SDTOP$_{general}$ would count neither p_{ij} nor p_{ji} when these simultaneous arrivals (simultaneous only in the sense that they are within a large ϵ of each other) occur. SDTOP$_{noSimul}$ would explicitly forbid such arrivals. For large enough ϵ, it is unlikely that no two nodes will be within $N\epsilon$ units of each. For large enough ϵ, constraint (K22) can unnecessarily become infeasible. Thus, for very large ϵ it is preferable to use SDTOP$_{noSimul}$.

It is possible that the optimal solution value, $sdtop^*$, corresponds to more than one unique solution. In this situation, the minimum-distance route is preferable. This can be achieved by solving a second SDTOP in which a constraint is added requiring that the total profit equal $sdtop^*$ and the objective function minimizes the total distance of the routes.

K.5 Number of variables and constraints

The three formulations for the SDTOP that we have presented are more complex than the standard VRP and TOP formulations. We added variables and constraints to model requirements such as explicitly forbidding simultaneous arrivals.

Table K-1: Numbers of variables and constraint for three SDTOP formulations.

$V_1 = (N+1)(K+NK+1)+N+K$ $V_2 = (N+1)(K+NK+1)+K$ $C = 2K((N+1)+N^2+1.5)+NK+2(N+1)$			
	SDTOP$_{simp}$	SDTOP$_{general}$	SDTOP$_{noSimul}$
Total number of variables	$V_1+4N(N-1)$	$V_1+7N(N-1)$	$V_1+7N(N-1)$
Number of binary variables	V_1+3N^2-4N-1	V_1+5N^2-6N-1	V_1+5N^2-6N-1
Number of continuous variables	N^2+1	$2N^2-N+1$	$2N^2-N+1$
Number of constraints	$C+7N(N-1)$	$C+16N(N-1)$	$C+16N(N-1)$
Minimum variable formulations			
Total number of variables	$V_2+3N(N-1)$	$V_2+6N(N-1)$	$V_2+6N(N-1)$
Number of binary variables	V_2+3N^2-4N-1	V_2+5N^2-6N-1	V_2+5N^2-6N-1
Number of continuous variables	$N+1$	N^2+1	N^2+1
Number of constraints	$C+6N(N-1)$	$C+15N(N-1)$	$C+15N(N-1)$

The formulations produce linear relaxations that are too weak to use in the branch-and-bound process. Because of this, we have been unsuccessful in trying to solve problems with more than 10 nodes and one vehicle although problems with up to five nodes and three vehicles solve in seconds.

In Table K.5, we show the number of variables and constraints in the three formulations where we allow different depots, maximum tour lengths, and maximum capacities for each vehicle. Giving every vehicle the same starting and ending depot, maximum tour length, and maximum capacity reduces complexity only marginally. The majority of the binary variables are used to determine the meta-route sequence in order to evaluate the objective function. Each formulation has $O(N^2K)$ complexity for both variables and constraints.

Appendix L

CETSP/CEVRP Problem Data

In this appendix, we present the problem data for all CETSP and CEVRP instances. The six problems whose names begin with *team* along with the *bonus*1000 problem are collectively denoted the *Team* problems. The problems whose names begin with *rotatingDiamonds*, *bubbles*, or *concentricCircles*, along with *chaoSingleDep*, are collectively denoted the *Geometric* problems. The seven problems created from TSPLIB instances are referred to as the *TSPLIB* problems.

The data for each problem are presented in the following tables. Each table has six columns. Node ID numbers each node in the problem, where node 0 represents the depot. Counting the depot, the *Team* problems have one more node than their names imply. That is, including the depot, *team*1_100 has 101 nodes. Including the depot, the *TSPLIB* problems have exactly the number of nodes as their names imply. The second, third, and fourth columns give the coordinates for each node where the z-coordinates are only relevant for the 3D versions of problems. The fifth column gives the radius of each node for the arbitrary radius versions of the problem. The sixth column gives each node's demand. Node demands are only relevant to CEVRP problems. Each table lists the maximum vehicle capacity and tour length for CEVRP problems.

The *Team* problems each have one fixed-radius scenario. For example, as shown in Table L-1, for the fixed-radius version of *team*1_100, $r_i = 9$ for all i.

The $TSPLIB$ problems have three fixed-radius scenarios, low overlap ratio (0.02), medium overlap ratio (0.1), and high overlap ratio (0.3). For example, consider $kroD100$, as shown in Table L-8. For low overlap ratio, $r_i = 0.7798$ for all i, for medium overlap ratio, $r_i = 3.899$ for all i, and for high overlap ratio, $r_i = 11.697$ for all i.

The *Geometric* problems were created solely for 2D, fixed-radius experiments. Therefore, all z-coordinates are 0 and the radii for all nodes in problem are equal. Data for the five *rotatingDiamonds* and the five *concentricCircles* problems are given in Tables L-15 and L-16. The nodes used and the vehicle capacities for both sets of problems are given in Table L-17. Data for *bubbles*2 to *bubbles*9 are given in Table L-20. The nodes used and the vehicle capacities are given in Table L-19.

The nodes for each problem are shown in 2D and also 3D, if relevant. x-coordinates have been shifted right 110 units and y-coordinates are graphed with the sign flipped. In the 2D (3D) figures, the depot is shown as disk (sphere) slightly larger than the nodes.

The author can be reached at `wmennell@hotmail.com` for copies of the data files.

Appendix M

SDTOP Problem Data

In this appendix, we present the problem data for all SDTOP instances. The problems are created from the 130 TOP problems given in Archetti et al. [6]. Each of the 10 unique node sets are given different combinations of maximum vehicle capacity, maximum tour length, and number of vehicles available to create the 130 problems and are divided into Set I, Set II, and Set III. To make SDTOP problems we added an inverse symmetric reward matrix P for each of the 10 node sets.

We created 10 additional, heterogeneous-fleet problems, called Set IV, based on the 10 Archetti et al. node sets. All Set IV problems can achieve the LOP solutions found by Charon and Hudry's code. The reward matrix, P, is generalized. The number of vehicles available for use, K, is not necessarily equal to the maximum number that can be used in any solution, k_{max}. The minimum number of vehicles that must be used, k_{min}, is not necessarily equal to one.

For all problems, the p_{ij} values for any matrix P are uniformly distributed on the interval [0, n] for a generalized P and [-n, n] for an inverse symmetric P. All problems use the 2D, Euclidean norm although our method can solve problems using the Euclidean 3D, Manhattan 2D, and Manhattan 3D norms.

The data for each of the 10 unique node sets problem are presented in Tables M-1 through M-10. Following each table, the inverse symmetric P and the generalized P associated with that problem are given. Tables M-11 through M-14 present the maximum

capacities, tour lengths, number of vehicles that can be used, and which P matrix is associated with each problem.

The author can be reached at `wmennell@hotmail.com` for copies of the data files include P matrices.
