

ABSTRACT

Title of Document: AN RNA:DNA-BASED INDEX OF GROWTH IN JUVENILE ATLANTIC MENHADEN (*BREVOORTIA TYRANNUS*): LABORATORY CALIBRATION AND FIELD ASSESSMENT

Jason Lee Edwards, Master of Science, 2009

Directed By: Professor Thomas J. Miller, University of Maryland Center for Environmental Science, Chesapeake Biological Laboratory

Atlantic menhaden (*Brevoortia tyrannus*) is an ecologically and economically important species in the mid-Atlantic coastal ecosystem. Its population dynamics are influenced by growth and survival during juvenile occupancy in estuarine nursery habitats. Therefore, quantifying production of potential nursery areas is important to understanding population processes and defining essential fish habitat for this species. Based on laboratory growth experiments, an RNA:DNA-based growth model was developed for young-of-the-year menhaden. The temporal response of RNA:DNA to changes in feeding condition was also quantified in the laboratory. Results of these investigations indicate RNA:DNA as a reliable tool for estimating recent growth and condition in relation to habitat residency. RNA:DNA-based estimates of growth were combined with site-specific abundance estimates to evaluate the spatiotemporal variability in production of potential menhaden nursery habitats. Site-specific production estimates exhibited high spatiotemporal variability suggesting menhaden utilize a mosaic of habitats to promote production, rather than specific sites consistently generating high levels of production.

AN RNA:DNA-BASED INDEX OF GROWTH IN JUVENILE ATLANTIC
MENHADEN (*BREVOORTIA TYRANNUS*): LABORATORY CALIBRATION
AND FIELD ASSESSMENT

This work is dedicated to my mother and father, who questioned me in nothing and supported me in everything. Thank you.

Acknowledgements

First and foremost, I would like to thank my advisor, Dr. Thomas J. Miller. The combination of guidance, support and independence he has provided has truly made this a worthwhile experience. Special thanks must go to my committee for their valuable input on my education and research. Also, I would like to thank the Miller lab group including David Loewensteiner, Janet Nye and Adam Peer. I would not have made it through this process without them. Many thanks to all who helped with the field, lab and conceptual components of this research including Tom Ihde, Mike Wilberg, Kara Schroepfer, Sarah Michaels, Megan Gluth, Chris Cammarata, Jamie Smith and Rebecca Wingate. I would also like to thank Tim Targett's lab, especially Ben Ciotti and Catherine House for their help with sample collection and RNA:DNA analysis. I must thank Bud Millsaps for his help with the seawater facility during my experiments. I would also like to express my sincere gratitude to Joe Drach and Patricia Mickelson for their great generosity to CBL and their support of my endeavor to "Save the Bay." With the help individuals like them, we may actually do just that. I must also thank my friends both at CBL and afar who have provided lots of support, encouragement and laughs over the past three years. Special thanks must go to Jaime Aulson who always made me smile, even when science wasn't nice to me. Thank you for sticking with me through all this. Lastly, I must thank the 2008 year-class of Atlantic menhaden. Without them, none of this would have been possible. Thanks to everyone for all you have done. It has been greatly appreciated.

Chapter 1:
Rationale

Introduction

Estuarine environments provide important nursery habitats for many ecologically and economically important fishes during critical periods of early life (June & Chamberlain 1959, Weinstein 1979, Nixon 1980, Hoss & Thayer 1993, Able & Fahay 1998, Beck et al. 2001, Minello et al. 2003). Estuarine nursery habitats are generally characterized as providing favorable physicochemical conditions (e.g. temperature, salinity, dissolved oxygen), abundant and/or high quality prey resources and decreased predation risk. Many of these factors influence growth or survival of fish early life stages (Miller et al. 1985, Beck et al. 2001). Furthermore, variability in growth during early life stages can have considerable influence on survival and subsequent recruitment of fishes (Houde 1987). For example, increased growth rates normally confer a survival advantage in larval and juvenile fishes by ushering individuals more quickly through size-selective predation fields (reduced stage-duration) and decreasing over-winter mortality (Houde 1987, Post & Evans 1989a, Post & Evans 1989b, Rice et al. 1993a, Rice et al. 1993b, Meekan & Fortier 1996, Conover & Schultz 1997, Sogard 1997, Takasuka et al. 2004, Takahashi et al. 2008). Growth and survival of fish early life stages, and the interaction of these two processes can have complex and nonlinear impacts on the potential of different estuarine habitats to serve as nursery areas.

To date, insufficient consideration has been given to the criteria for designation of specific estuarine environments as nursery habitats. Beck et al. (2001) assert that the custom of indiscriminately classifying all juvenile habitats as nurseries serves no purpose in focusing conservation and management efforts. Furthermore,

many studies examining nursery areas have ignored fundamental factors contributing to the relative importance of specific nursery habitats. Within and among estuaries, nursery habitats are not uniformly productive. Beck et al. (2001) suggest the importance of a nursery area is determined by the relative contribution it makes to the recruitment of individuals to the adult population and therefore, defined a nursery as a habitat that, on average, produces disproportionately more recruits per unit area than do other habitats in which individuals of a particular species occur. Beck et al. (2001) identify the following four factors that combine to influence the relative contribution a specific nursery habitat makes to recruitment: (1) abundance, (2) growth, (3) survival, and (4) movement of individuals. Few studies, however, have incorporated information on these factors in a formal quantitative examination of relative contribution of different nursery habitats. For instance, habitat-specific abundance estimates (number of individuals per unit area) have often been used as an indicator of habitat quality; although, this measurement alone provides no information on the proportion of individuals surviving to adulthood. Because the contribution a habitat makes to adult recruitment is a product of multiple variables, Beck et al. (2001) affirm that an integrated measure of some, if not all of the aforementioned factors is necessary to assess potential nursery habitats. An integrated habitat metric can be used to determine which juvenile habitats serve as nurseries, facilitating the prioritization of spatially-explicit management, restoration and conservation efforts. Additionally, comparing relative habitats values will aid in the identification of biotic and abiotic factors contributing to site-specific spatiotemporal variability in habitat

production, which may improve our understanding of population and recruitment dynamics.

The concept of essential fish habitat (EFH) provides a framework to identify and evaluate the contribution of different estuarine nursery areas. The Magnuson-Stevens Fishery Conservation and Management Reauthorization Act (MSFCMRA - 2007) defined EFH as *those waters and substrate necessary to fish for spawning, breeding, feeding, or growth to maturity* (NOAA 2007). The National Marine Fisheries Service (NMFS) has developed four levels of resolution in defining EFH as mandated by the MSFCMRA (NMFS 1997). The first two levels of EFH require information on presence/absence and relative abundance data of a species or life history stage, respectively (Able 1999). The third level of EFH requires data regarding habitat-related growth, reproduction and/or survival by life history stage, adding that habitats exhibiting the highest production should support the highest levels of these measures (Able 1999). The fourth level of EFH requires a quantitative description of habitat production, defining essential fish habitats as those necessary to maintain fish production consistent with a sustainable fishery and healthy ecosystem (Able 1999).

While all levels of information outlined by the NMFS are potentially important in determining EFH, the categories that specifically facilitate quantification of habitat production to accurately define and compare EFH are perhaps most valuable. The two highest levels of EFH designation rely on quantification of habitat-specific growth. Growth during early life stages influences survival and recruitment (Rice et al. 1993b). Habitats promoting rapid growth are therefore likely important to

recruitment in fishes. In turn, because growth responds to habitat characteristics such as physicochemical factors (Fry 1971) and prey availability (Graeb et al. 2004), *in situ* growth rates likely reflect habitat quality (Sogard 1992, Meng et al. 2000, Nislow & Folt 2000, Le Pape et al. 2003, Amara et al. 2007, Glass et al. 2008). Ultimately, to meet the highest level of EFH designation, estimates of growth (g.t^{-1}) must be combined with estimates of abundance to provide an index of relative production, hereafter production. Inherently, these solitary production estimates exclude the impact of mortality on habitat contribution; however, estimates generated from the coupling of these measures provide “snapshots” of site-specific production. Therefore, mortality influences these snapshots by reducing abundance between sampling events. Estimates of habitat-specific abundance, defined as the number of individuals per unit area (m^{-2}), can provide important information regarding relative habitat use by fishes (Able 1999, Beck et al. 2001) and are an integral part of estimating production. Unfortunately, the quantification of habitat-specific production ($\text{g.m}^{-2}.\text{t}^{-1}$) has posed a major challenge to investigators (Edgar & Shaw 1995, Able 1999, Beck et al. 2001, Gillanders et al. 2003).

Reliable estimates of habitat-specific abundance data can be obtained without difficulty. However, most traditional methods of estimating growth, such as size-at-age and otolith-based techniques integrate past growth over protracted time periods. Therefore, these approaches to estimating growth in mobile organisms, such as juvenile fishes, likely integrate growth over multiple habitats. Consequently, such growth estimates may not match, spatially or temporally, estimates of relative habitat-specific abundance, potentially providing unreliable estimates of habitat-specific

production. Thus, a central problem in producing estimates of production of specific habitats is the availability of growth estimates at relevant spatial and temporal scales such that they reliably reflect recent growth in the habitat of interest.

Nucleic acids levels within tissues can provide an index of growth. The underlying principle of the approach is that the amount of deoxyribonucleic acid (DNA) remains constant within individual cells of an organism. Conversely, ribonucleic acid (RNA) levels fluctuate in response to activity of the protein synthetic machinery on the ribosomes. Thus, during periods of increased growth and cellular division, RNA levels increase while DNA amounts remain invariable, producing relatively higher RNA:DNA (Bulow 1970, Buckley et al. 1984, Ferron & Leggett 1994). RNA-DNA ratios have been used as an index of growth in cell and tissue cultures (Dortch et al. 1983), and in whole organisms (Sutcliffe 1970). In fishes, RNA-DNA ratios have been found to reliably estimate growth of larval (e.g., Wright & Martin 1985, Rooker & Holt 1996, Heyer et al. 2001) and juvenile fish (Malloy & Targett 1994a, Suthers et al. 1996, Smith & Buckley 2003). Because RNA levels reflect physiological conditions, RNA levels respond over relatively short time scales. Thus, RNA-DNA ratios can be associated with environmental conditions observed at the time of sampling events (Buckley 1984, Bulow 1987, Ferron & Leggett 1994, Buckley et al. 1999). Importantly for estimating habitat-specific growth rates, RNA-DNA ratios have also been found to respond to changes in feeding and growth on the order of hours to days, making them a valuable resource for measuring habitat-specific growth (Wright & Martin 1985, Bulow 1987, Ferron & Leggett 1994, Malloy & Targett 1994b, Arndt et al. 1996, Kono et al. 2003, Catalan et al. 2007, Stierhoff et

al. 2009). RNA:DNA offers a valuable tool for identifying and understanding the relationships between recent growth, production and environmental factors of estuarine nursery habitats.

However, the principal challenge in the application of RNA:DNA-based approaches in estimating habitat-specific production is that RNA:DNA ratios provide an index of growth and not an absolute estimate. Various studies have quantified the relationship between RNA:DNA and growth rate to estimate condition and growth of laboratory and field collected fish (Buckley 1982, Buckley et al. 1984, Caldarone 2005, Mercaldo-Allen et al. 2006, Mercaldo-Allen et al. 2008). Because activity of ribosomal RNA increases with temperature (Buckley 1982, Buckley et al. 1999), some relationships developed to estimate growth from RNA:DNA have been improved by the inclusion of temperature in the model (Buckley 1982, Buckley et al. 1984, Caldarone et al. 2003, Caldarone 2005, Mercaldo-Allen et al. 2006). The majority of relationships between RNA:DNA and growth have been found to be species-specific, meaning that relationships determined for one species may not be reliably applied to another. These findings suggest that any proposed application of an RNA:DNA-based growth index to previously untested species requires laboratory quantification of the relationship between RNA:DNA, temperature and growth rate. Once a laboratory-based predictive model has been developed, inputs of RNA:DNA from field-caught individuals and observed temperatures from sampling sites may be used to estimate growth of resident fish and the associated production of estuarine nursery habitats.

Several different biochemical approaches to quantifying nucleic acids have been published. The majority of these techniques involve binding a fluorescent dye or fluorochrome to the nucleic acids (Clemmesen 1993). The techniques differ in the detergents used to break down the lipoprotein membranes that surround the cell and in the fluorochromes used. It is known that these different protocols affect the RNA:DNA values calculated (Caldarone et al. 2006). Thus, different protocols will yield different absolute RNA:DNA values for the same sample. Recently, Caldarone et al. (2006) demonstrated an approach that standardizes RNA:DNA values calculated by different protocols. The approach uses the slopes of the calibration curves that express fluorescence as a function of known nucleic acid concentrations to standardize the sensitivity of each protocol to different nucleic acid concentrations.

Here I apply RNA:DNA-indices of growth to quantify production in juvenile Atlantic menhaden (*Brevoortia tyrannus*) during periods of estuarine residency. Atlantic menhaden (hereafter menhaden) is an ecologically and economically important species in the mid-Atlantic ecosystem, providing important ecosystem services as a filter feeder and forage species and supporting a valuable commercial fishery (ASMFC 2006). Menhaden is a schooling, obligate filter-feeding planktivore which consumes a mixture of phytoplankton, zooplankton and detritus in proportion to concentrations found in the environment (Jeffries 1975). Menhaden schools filter large quantities of water, potentially limiting phytoplankton blooms and increasing water clarity. These ecosystem services can be especially valuable when anthropogenic sources of nutrient inputs stress marine environments. In turn, menhaden juveniles and adults represent an important prey for many piscivorous

fishes (Sykes & Manooch 1979, Hartman 2003, Uphoff 2003), birds (Spitzer 1989) and marine mammals (Hildebrand 1963). Thus, menhaden represents an important trophic link between primary and secondary production and higher trophic levels, circulating and redistributing considerable amounts of energy throughout the mid-Atlantic ecosystem (Peters & Schaaf 1981, Lewis & Peters 1984).

Economically, menhaden supports valuable commercial reduction and bait industries. In 2007, the commercial harvest of Atlantic menhaden was 215,506 metric tons valued at nearly 32 million dollars (NMFS 2008). The reduction fishery utilizes purse-seining gear to harvest vast numbers of menhaden which are subsequently processed into fish meal, fish oil and condensed fish solubles for products such as agri- and aquaculture feed, food additives, paints, cosmetics, health supplements and fertilizers (Smith 1991). A relatively smaller bait industry exists for menhaden; although, landings of this sector have become more important to the total catch in recent years (ASMFC 2006).

Atlantic menhaden ranges from Nova Scotia to central Florida (Reintjes 1969, Ahrenholz 1991). During the summer, adult menhaden are stratified by age and size, with the oldest, largest individuals found at the highest latitudes (Nicholson 1978, Ahrenholz 1991). In fall, menhaden begin their southern migration. Some spawning occurs year round (Higham & Nicholson 1964, Judy & Lewis 1983, Warlen 1994), but the most intense spawning is believed to occur from December through March south of Cape Hatteras, North Carolina (Higham & Nicholson 1964, Reintjes & Pacheco 1966, Judy & Lewis 1983). After spawning peaks, schools migrate north beginning in late March/early April. During the northern migration, spawning occurs

at a decreasing rate and progressively farther inshore (Rogers & Van Den Avyle 1989). By May, most spawning is restricted to areas north of Cape Hatteras (Judy & Lewis 1983). Spawning reaches its minimum in June when individuals are again dispersed from Maine to Florida (Judy & Lewis 1983).

Estuarine systems along the Atlantic seaboard are important habitats for juvenile menhaden. Eggs typically hatch at sea between 2.5 – 2.9 days at 15.5°C (Hettler 1981) with a size at hatch between 3 – 4 mm (Powell & Phonlor 1986, Maillet & Checkley 1990, Warlen 1992). Menhaden larvae are transported from their coastal spawning sites to estuarine habitats by a combination of physical processes and behavioral responses, arriving at various estuaries along the coast at different times depending upon factors such as spawning time and location (Reintjes & Pacheco 1966, Nelson et al. 1977, Checkley et al. 1988, Warlen 1994, Quinlan et al. 1999, Hare et al. 2005). Menhaden typically spend 1-3 months at sea and are normally still larvae (8-42 mm total length [TL]) when they ingress into estuarine environments (June & Chamberlain 1959, Reintjes & Pacheco 1966). The mean age and standard length of larvae recruiting to the New Port River estuary, N.C. was 61 days and 24.6 mm over seven spawning seasons (Warlen 1994). Ingress generally occurs during May – October in the North Atlantic, October – June in the Mid-Atlantic, and November – May in the South Atlantic (Reintjes & Pacheco 1966, Wilkens & Lewis 1971). Once in the estuaries, menhaden prefer shallow, low salinity environments in which they metamorphose to the juvenile stage (Wilkens & Lewis 1971, Weinstein 1979, Rogers et al. 1984, Murdy et al. 1997).

The transition from the larval to the juvenile stage occurs at around 38 mm (Lewis et al 1972) and is characterized by a morphological change in feeding apparatus, allowing a dietary shift from individual zooplankton prey to filter-feeding on plankton and other suspended organic matter (June & Carlson 1971). Generally, juveniles experience rapid and variable growth rates during estuarine residency, influenced primarily by environmental conditions and prey availability. Juveniles have shown growth rates approaching 1 mm/day in the field (Reintjes 1969, Kroger et al. 1974). During fall, growth is effectively halted when temperatures drop below 15°C (Kroger et al. 1974) when most will leave the estuarine environment and join the adult stock on their southward migration. Lengths of emigrating juveniles typically range from approximately 55 to 140 mm TL (Nicholson 1978).

Estuarine nursery habitats are critical to the growth and survival of early life history stages of Atlantic menhaden. The most recent ASMFC stock assessment showed that coastwide juvenile menhaden abundance indices have declined since the 1970s, although the adult spawning population remains healthy (ASMFC 2006). Specifically in the Chesapeake Bay, bay-wide indices of juvenile abundance have experienced similar declines (Durell & Weedon 2007 – Figure 1.1). The causes of the recent menhaden recruitment declines have yet to be determined, but may be attributed to environmental influences (Wood 2000). In the Chesapeake Bay, decreased survival during estuarine residency has been cited as a potential cause of recent poor recruitment episodes (ASMFC 2004). Using a matrix modeling approach, Quinlan & Crowder (1999) identified growth and mortality dynamics in the late larval and juvenile stages to be most important to population growth rates of

menhaden. These life stages coincide with periods of estuarine residency, suggesting that processes occurring during juvenile occupancy of estuarine nursery habitats may have great influence on menhaden population dynamics. Therefore, examination of nursery ground processes and their effects on juvenile menhaden could provide valuable information for understanding menhaden population dynamics, improving recruitment predictions, defining essential fish habitat and developing effective management strategies for this species.

Information on the abundance of juvenile menhaden in mid-Atlantic estuaries is important not only for understanding the dynamics of its own species, but also for the dynamics of a major predator, striped bass (*Morone saxatilis*). Several studies have documented the importance of Atlantic menhaden to the diet of striped bass (Hartman & Brandt 1995, Walter & Austin 2003, Walter et al. 2003). While menhaden numbers have been declining, striped bass abundance is currently at historically high levels, increasing the relative demand for menhaden as prey. In fact, recent observations of emaciation and occurrences of mycobacteriosis in striped bass may be a result of insufficient numbers of menhaden as forage (Uphoff 2003). Thus, understanding the dynamics of menhaden has important consequences for advancing ecosystem-based approaches to fisheries management.

In this study, I have attempted to evaluate the spatial and temporal dynamics of estuarine nursery habitats of Atlantic menhaden by quantifying site-specific habitat production in Chesapeake and Delaware Bays. Potential nursery habitat production was determined by combining nucleic acid-based estimates of growth with fishery-independent abundance data. Relative habitat production was then compared over a

range of scales both spatially and temporally to better define essential fish habitat and investigate the potential factors determining recruitment success for this species.

Objectives

The objectives of this study were to 1) develop an RNA:DNA-based index for estimating growth rate in juvenile Atlantic menhaden by experimentally quantifying the relationship between growth rate, temperature and RNA:DNA, 2) determine the temporal response (latency) of nucleic acid-based condition to changes in feeding status in juvenile Atlantic menhaden, 3) combine nucleic-acid based growth estimates with fishery-independent abundance data to compare relative nursery habitat production on both broad- and fine-scales for juvenile Atlantic menhaden in the Chesapeake and Delaware Bays. Each objective is addressed in a subsequent chapter of my thesis, with each chapter prepared as a draft manuscript intended for submission for publication to peer-reviewed journals. I will be senior author on all publications derived from this thesis. The target journals have yet to be defined.

Chapter 2:

**An RNA:DNA-based model for estimating growth rate of
juvenile Atlantic menhaden *Brevoortia tyrannus***

Abstract

Fluorometric techniques were used to develop a nucleic acid-based index for estimating instantaneous growth rate in young-of-the-year Atlantic menhaden. A series of 10-day laboratory growth experiments consisting of different temperatures and food rations was conducted. Weight-specific instantaneous growth rate and nucleic acid measurements (RNA content, DNA content, RNA:DNA) were obtained from individual fish. RNA:DNA was most correlated with instantaneous growth (G) ($r = 0.81$; $p < 0.0001$). Using multiple linear regression, RNA:DNA and temperature explained 76% of the variability in growth, producing the following predictive model: $G = 0.01021(\text{RNA:DNA}) + 0.00199(T) - 0.09929$. This model can be applied to field-caught individuals to estimate relative growth in potential nursery habitats for juvenile Atlantic menhaden.

Introduction

Estuarine environments provide important nursery habitats for many ecologically and economically important fish species (June & Chamberlain 1959, Weinstein 1979, Nixon 1980, Hoss & Thayer 1993, Able & Fahay 1998, Minello et al. 2003). Estuarine nursery habitats are believed to foster increased growth and survival of early life stages by providing favorable abiotic conditions, sufficient prey resources and decreased predation risk (Miller et al. 1985). The nursery-role concept proposed by Beck et al. (2001) defined nurseries as habitats that contribute disproportionately more recruits to the adult population than other habitats by providing favorable conditions for growth and survival during early life stages. However, the quality and relative value of nursery habitats within and among estuaries is not homogeneous. Determining which habitats constitute nurseries may help to identify the factors influencing spatiotemporal habitat variability, potentially increasing our understanding of recruitment dynamics and improving management strategies for estuarine dependent fish species.

Identification of which habitats may function as nurseries requires quantification of habitat-specific production. Production ($\text{g}\cdot\text{m}^{-2}\cdot\text{d}^{-1}$) is typically defined as the product of abundance in the habitat (number of individuals), the area of the habitat (m^{-2}) and the net individual growth rate in the habitat ($\text{g}\cdot\text{d}^{-1}$). However, growth and production likely do not vary proportionally as a result of the complex and potentially nonlinear relationship between growth during early life stages and survival and subsequent recruitment of fishes (Rice et al. 1993b). Increased growth rate normally confers a survival advantage in larval and juvenile fishes by reducing

stage-duration and decreasing mortality (Houde 1987, Post & Evans 1989a, Post & Evans 1989b, Rice et al. 1993a, Rice et al. 1993b, Conover & Schultz 1997, Sogard 1997). Also, because growth responds to variability in nursery habitat characteristics such as physicochemical factors (Fry 1971) and prey availability (Graeb et al. 2004), growth indices may provide a useful measure of habitat-specific production or quality (Sogard 1992, Meng et al. 2000, Nislow & Folt 2000, Le Pape et al. 2003, Amara et al. 2007, Glass et al. 2008).

For estimates of growth rates to be of utility in quantifying habitat-specific production, it is critical that only growth achieved while the animals are in the specific habitat be measured. Biases in the estimates of habitat-specific production can be introduced if growth that occurred while the animals are in different habitats is incorporated into the estimated growth and hence, into estimates of production. Thus, the approach used to estimate growth must have a temporal resolution shorter than the period of residency of the animals in the habitat, but must integrate the temporal variability in the characteristics of the habitat itself. Many traditional methods of estimating growth, such as size-at-age and otolith-based techniques integrate past growth over protracted time periods and potentially, multiple habitats. These estimates likely do not correspond to site-specific abundance estimates, potentially providing unreliable estimates of habitat-specific production.

Nucleic acid-based condition indices offer a means to estimate growth over short temporal scales, thereby providing a higher spatial resolution corresponding to site-specific abundance estimates. The underlying principle behind the use of RNA:DNA indices is that DNA content remains relatively constant per cell, reflecting

cell number. Conversely, RNA content fluctuates in response to the amount protein synthetic machinery and ribosomal activity, providing a measure of relative condition and potential growth of individuals (Bulow 1970, Buckley et al. 1984, Ferron & Leggett 1994). RNA:DNA has been used historically to estimate growth in cell and tissue cultures (Dortsch et al. 1983), and in whole organisms (Sutcliffe 1970). Because environmental variables (e.g. temperature, salinity, dissolved oxygen) and site-specific availability of potential prey vary over small spatial and temporal scales, RNA:DNA offers a valuable tool for identifying and understanding the relationships between recent growth, production and environmental factors of estuarine nursery habitats.

Numerous studies have quantified the relationship between RNA:DNA and growth rate to estimate condition and growth of laboratory and field collected fish (e.g., Buckley 1982, Buckley et al. 1984, Caldarone 2005, Mercaldo-Allen et al. 2006, Mercaldo-Allen et al. 2008). RNA-DNA ratios have been found to reliably estimate recent feeding and growth of larval and juvenile fish (Wright & Martin 1985, Malloy & Targett 1994a, Malloy & Targett 1994b, Rooker & Holt 1996, Suthers et al. 1996, Smith & Buckley 2003). Because activity of ribosomal RNA increases with temperature (Buckley 1982, Buckley et al. 1999), some relationships developed to estimate growth from RNA:DNA have been improved by the inclusion of temperature in the model (Buckley 1982, Buckley et al. 1984, Caldarone et al. 2003, Caldarone 2005, Mercaldo-Allen et al. 2006). Additionally, relationships between RNA:DNA and growth have normally been found to be species specific, meaning that relationships determined for one species may not be reliably applied to another.

These findings suggest that any proposed application of an RNA:DNA-based growth index to previously untested species requires laboratory quantification of the potential relationships between RNA:DNA, temperature and growth rate. Once a laboratory-based predictive model has been developed, inputs of RNA:DNA from field-caught individuals and observed temperatures from sampling sites can be used to estimate growth of resident fish and the associated production of estuarine nursery habitats.

In this study, I conducted laboratory experiments to determine the relationship between RNA:DNA, temperature and growth rate of juvenile Atlantic menhaden (*Brevoortia tyrannus*) using a fluorometric 1-dye/2-enzyme microplate assay.

Menhaden is an ecologically and economically important species in mid-Atlantic ecosystems, providing important ecosystem services as a filter feeder (Peters & Schaaf 1981, Lewis & Peters 1984) and forage species (Uphoff 2003) and supporting a valuable commercial fishery (Ahrenholz et al. 1987). Menhaden generally spawn in continental shelf waters (Higham & Nicholson 1964, Judy & Lewis 1983) and larvae are transported to various estuaries along the Atlantic coast (Quinlan et al. 1999).

Juvenile menhaden are estuarine-dependent during their first year of life, and processes affecting the juvenile stage likely have major influence upon population growth rates (Quinlan & Crowder 1999). Recent stock assessments have shown that juvenile menhaden abundance indices have declined since the 1970s (ASMFC 2006), suggesting the need for investigation into the potential mechanisms contributing to decreased recruitment success. Examination of nursery ground processes and their effects on juvenile menhaden could provide valuable information for understanding

menhaden recruitment variability, defining essential fish habitat and developing effective management strategies for this species.

Materials and Methods

Growth experiments

Experiments were conducted using young-of-the-year, juvenile Atlantic menhaden collected by beach seine from littoral habitats in the Patuxent River, MD. Fish were held for at least seven days to allow recovery from transportation or handling-induced stress, and acclimated to experimental temperatures for at least an additional five days before undergoing experimentation. During this period, fish were fed pelleted food (Zeigler Finfish Starter Meal, Gardners, PA, 0.42- 0.595 mm) *ad libitum* four times daily. Individuals showing signs of injury or disease were not used in the experiments. A photoperiod of 14 hr light – 10 hr dark was imposed throughout all phases of the research.

A laboratory growth experiment involving four, 10-day growth trials incorporating a range of temperature and feeding regimes was conducted between May 23 and September 8, 2008. Fish used in the experiments ranged from 0.76 – 36.94 g (Table 2.1). Temperature and food ration levels were chosen to elicit a wide range of growth rates and to simulate the approximate thermal regime that juvenile menhaden experience during estuarine residence in the Chesapeake Bay and other mid-Atlantic estuaries. Treatment combinations used in trials were established using a response surface methodological approach. This design consisted of a core set of levels of each factor (i.e., temperatures: 20, 24, 28°C and rations: 0, 5, 20% body wt.day⁻¹) conducted as a two-factor randomized complete block design with

additional levels incorporated to fully quantify relationships between temperature, ration, growth and RNA:DNA. Trials 1 and 2 consisted of three levels of temperature (20, 24 and 28°C) and three food rations (0, 5 and 20% body wt.day⁻¹). Trials 3 and 4 consisted of four levels of temperature (20, 24, 28 and 30°C) and three food rations (0, 5 and 20% body wt.day⁻¹). To ensure the feeding regime produced a wide spectrum of growth rates, the second trial included an additional ration level of 50% body wt.day⁻¹.

Each trial employed 12 circular, 511-l fiberglass tanks. Each tank was provided with flow through water from the Patuxent River. Because menhaden is a planktonic filter-feeder, serial filtration (10, 5 and 1 µm) of inflowing water was utilized to ensure reliable ration treatments were maintained. Water quality was monitored regularly during the experiment. To begin an experiment, 7-8 fish were randomly assigned to each tank. Prior to addition to the tank individual menhaden were anesthetized with 60mg.l⁻¹ MS-222, weighed, measured, and fin clipped for identification at the end of the experiment. Fish were fed their assigned ration level at regular intervals 4 times daily. After 10 d, fish from each tank were measured and weighed. Food was not withheld on day 10 so as to maintain treatment-related differences in biochemical indices. Fish were immediately frozen on dry ice and stored at -80°C after measuring and weighing for subsequent biochemical analyses.

Biochemical analyses

Nucleic acid concentrations were determined using a 1 fluorochrome (ethidium bromide) / 2 enzyme (RNase and DNase) fluorometric protocol adapted from Caldarone et al. (2001) for use with juvenile fish. Three subsamples of epaxial

muscle tissue above the lateral line were removed from each fish. Each subsample was placed in 1% N-lauroylsarcosine for extraction, vortexed for 60 minutes, sonicated and vortexed again for 30 minutes to ensure complete dissociation of nucleoproteins. Subsamples were further diluted with tris-EDTA buffer and centrifuged to precipitate cellular debris. Aliquots were pipetted into a 96-well microplate. The fluorochrome ethidium bromide was added to each well and total nucleic acid fluorescence was measured using a spectrofluorometer (Spectramax II, Molecular Devices Inc., Sunnyvale, CA). The excitation wavelength was 525 nm and the emission wavelength was 600 nm. RNase and DNase were used to enzymatically digest RNA and DNA, respectively. Fluorescence values of RNA and DNA were determined via subtraction after the enzymatic digestion of each nucleic acid, respectively. Samples were run in triplicate in a randomized order on 81-well microplates. Calibration curves were produced for each plate using serially diluted commercial preparations of 18S + 28S Ribosomal RNA (Sigma R-0889) and calf thymus DNA (Sigma D-1501). Fitted calibration curves were never less than $R^2=0.99$. RNA and DNA fluorescences for individual samples were converted to RNA and DNA concentrations by comparison with their respective calibration curve and the standardization procedure in Caldarone et al. (2006) which adjusts the fluorescence for the slope of the calibration curve. A standard control homogenate of surplus fish was prepared and analyzed with each plate to verify the accuracy of the run. All nucleic acid data were reported and analyzed as the average of the triplicate samples.

Statistical analyses

Weight-specific instantaneous growth rate (G , d^{-1}) was calculated for each fish using the equation: $G = [(\ln W_{t_f} - \ln W_{t_i}) d^{-1}]$; where W_{t_f} = final wet weight, W_{t_i} = initial wet weight and d = number of days between measurements. Estimates of body mass, G , RNA content, DNA content and RNA:DNA were available for each individual fish sampled. However, to avoid pseudoreplication, all statistical analyses were conducted using tank mean values. Pearson product moment correlation analysis was used to examine the relationships between RNA:DNA, RNA content, DNA content, temperature, body mass and instantaneous growth rate. Two-way analysis of variance (ANOVA) was used to determine the effects of experimental temperature, ration level and their interactions on both instantaneous growth rate and RNA:DNA of juvenile menhaden. Subsequently, when statistically significant effects of growth on RNA:DNA were detected, stepwise multiple linear regression was employed to develop a predictive model for growth of juvenile Atlantic menhaden. Variables tested included RNA:DNA, temperature and body mass. Variables were selected for the model if they met the significance criteria for inclusion ($p < 0.05$). All statistical analyses were conducted using SAS 9.1 (SAS Institute, Cary, NC, USA) and SYSTAT 11 (SYSTAT Software, Inc., Point Richmond, CA, USA).

Results

Only five of the 336 fish used to quantify the relationship between growth and nucleic acid concentration died during this study. Menhaden used in experiments exhibited growth from -0.11 to $0.07 d^{-1}$ over 10 d trials. Tank mean instantaneous growth (\pm S.E.) varied from -0.05 ± 0.005 to $0.03 \pm 0.006 d^{-1}$ (Figure 2.1). Measured

RNA levels in individual samples ranged from 0.43 to 4.34 $\mu\text{g}\cdot\text{ml}^{-1}$ while DNA levels ranged from 0.10 to 0.72 $\mu\text{g}\cdot\text{ml}^{-1}$. Individual RNA:DNA values ranged from 1.57 to 12.03. Tank mean RNA:DNA (\pm S.E.) varied from 2.26 ± 0.14 to 8.60 ± 0.68 (Figure 2.2).

Pearson product moment correlation analysis showed a significant positive correlation between RNA and DNA content ($r = 0.38$; $p = 0.0071$ - Table 2.2).

RNA:DNA was also significantly positively correlated with RNA ($r = 0.70$; $p < 0.0001$), but showed a significant negative relationship to DNA ($r = -0.33$; $p < 0.022$).

Results indicated a significant ($p < 0.0001$) positive correlation between RNA:DNA and instantaneous growth rate (d^{-1}), which produced the strongest relationship of all the variables examined ($r = 0.81$). Additionally, both RNA ($r = -0.54$; $p < 0.0001$) and RNA:DNA ($r = -0.42$; $p = 0.003$) were significantly negatively correlated with temperature.

Analysis of variance indicated a significant effect of experimental ration on both instantaneous growth rate ($p < 0.0001$) and RNA:DNA ($p < 0.0001$) in juvenile menhaden. Experimental temperature had a significant effect on RNA:DNA ($p < 0.0001$), but did not significantly affect instantaneous growth ($p > 0.05$). No significant interactions between ration and temperature were observed on either growth rate ($p > 0.05$) or RNA:DNA ($p > 0.05$).

Growth was non-linear, but significantly related to experimental ration (Fig 2.1). The data were fitted to the equation:

$$G = y_0 + \alpha(1 - e^{-\beta r})$$

where G and r = instantaneous growth rate and ration, respectively; α , β and y_0 = constants. Parameter estimates are given in Table 2.3. Similarly, RNA:DNA and ration were also significantly, but non-linearly related (Fig. 2.2).

An inverse relationship was developed to estimate juvenile menhaden growth from RNA:DNA. A relatively strong linear relationship was observed between tank mean RNA:DNA and instantaneous growth rate (adj $R^2 = 0.64$) (Figure 2.3), even without accounting for the effect of temperature treatment. Inclusion of temperature effects further improved the relationship between RNA:DNA and instantaneous growth (Figure 2.4). RNA:DNA was not found to increase with increasing temperature. Rather, as temperature increased, increased growth was observed at lower RNA:DNA values.

Step-wise multiple linear regression was employed to develop a predictive model for growth of juvenile Atlantic menhaden. Of the variables examined, RNA:DNA was most strongly related to instantaneous growth (Table 2.2) and was the first variable included in the model (adj $R^2 = 0.64$, $p < 0.0001$, Table 2.4). Temperature was selected next (adj $R^2 = 0.12$, $p < 0.0001$). No other variables met the required significance level for entry. The best equation for predicting growth was:

$$G = 0.01021(\text{RNA:DNA}) + 0.00199(T) - 0.09929 \quad (\text{adj } R^2 = 0.76, p < 0.0001).$$

This predictive model can be used to estimate instantaneous growth of juvenile Atlantic menhaden with inputs of RNA:DNA and temperature (Figure 2.5).

Discussion

My results indicated that RNA:DNA, along with associated effects of temperature, may serve as a reliable predictor of growth rate in juvenile Atlantic

menhaden. The model developed from the experimental data indicated that 76% of the variability in juvenile menhaden growth could be explained by RNA:DNA and temperature. Most of the variability is accounted for by the nucleic acid ratio (64%), with temperature accounting for 12% of the remaining variability. Results indicated that RNA:DNA is linearly related to growth, regardless of whether overall growth is negative or positive. Similar relationships have been found between RNA:DNA and growth in other species of fishes (Rooker & Holt 1996, Fukuda et al 2001, Peck et al. 2003, Caldarone 2005, Mercaldo-Allen et al. 2006, Mercaldo-Allen et al. 2008). RNA and DNA content were also found to be significantly correlated with growth; however, the relationship between each of these biochemical indices and growth was not nearly as strong as to that of RNA:DNA. This suggests that RNA:DNA could provide growth estimates of sufficient reliability to be of use in calculating habitat-specific growth rates of juvenile Atlantic menhaden.

The strength of the relationship between RNA:DNA and growth is comparable to similar relationships reported in other larval and juvenile stages of fishes (Buckley et al. 1984, Caldarone 2005, Mercaldo-Allen et al. 2006, Mercaldo-Allen et al. 2008). Other studies have similarly observed that the inclusion of temperature has strengthened the relationship of RNA:DNA-growth models (Buckley 1982, Buckley et al. 1984, Caldarone et al. 2003, Caldarone 2005, Mercaldo-Allen et al. 2006). This is the result of enhanced metabolic activity of fish with increasing temperature, and a corresponding increase in the rate of protein synthesis and ribosomal activity (Mathers et al. 1992). However, increased growth at higher temperatures is generally not associated with increased RNA:DNA, but instead,

higher temperatures produce increased growth rates at a given RNA:DNA compared to lower temperatures (Buckley 1982, Goolish et al. 1984, Buckley et al. 1999, Caldarone et al. 2003, Caldarone 2005). Correlation analysis supports this pattern by indicating a significant negative relationship between temperature and RNA:DNA in juvenile Atlantic menhaden. Although this relationship indicates that RNA:DNA and temperature are not strictly independent, a violation of an assumption of linear regression; the relative strength of the correlation is acceptable for inclusion of both variables in the prediction model.

Instantaneous growth rate was significantly affected by experimental ration. As anticipated, in all experiments growth increased with increasing ration level. However, individuals in tanks subjected to the 50% body wt.d⁻¹ ration treatment did not experience considerably increased growth beyond that of our 20% body wt.d⁻¹ level, suggesting that ration levels were appropriate for producing a sufficiently broad growth spectrum. Similar asymptotic relationships between growth rate and feeding have been observed in previous studies (O'Connell & Raymond 1970, Wurtsbaugh & Davis 1977, Checkley 1984, Kiørboe et al. 1987). Specifically, Keller et al. (1990) observed a curvilinear relationship in Atlantic menhaden in which growth rates approached a maximum in relation to experimental feeding levels in a mesocosm study. Durbin & Durbin (1983) found similar asymptotic relationships between growth and plankton concentration in Atlantic menhaden. However, it is possible that the saturation of growth with respect to feeding level observed in this study is not a result of individual menhaden approaching maximum growth rates. Instead, the trend produced may be due to an inability of experimental individuals to entirely consume

their assigned ration. Menhaden are planktonic filter feeders and therefore acquire food by sieving prey particles from the water column. In my study, prey was not ubiquitous, but was instead provided at regular intervals each day of the experiment. If sinking rates of food occurred more quickly than individuals could acquire it, individuals may not be able to achieve maximum ingestion. I attempted to eliminate this concern by feeding four times throughout the day, but insufficient ingestion may still have occurred. For the purposes of this study, however, the question of whether maximum growth was achieved may be unimportant as the saturation occurred at ration levels above those expected in the field.

Temperature, however, did not have a significant affect on growth rates. Generally, under maximum consumption conditions, increases in temperature will produce increased growth until temperature reaches a threshold at which growth will begin to decline, whereas, at low consumption, growth declines as temperature increases (Wooten 1998). Other studies have observed the effect of temperature on early life stages of Atlantic menhaden (Lewis & Hettler 1968, Hettler 1976, McNatt & Rice 2004). In my study, however, individuals were subjected to a range of temperature treatments designed to approximately simulate the thermal regime experienced by juvenile menhaden during estuarine residence time in the Chesapeake and Delaware Bays. Brandt & Mason (2003) state that at high feeding levels, juvenile menhaden have a relatively broad scope for growth, ranging from 21-30°C, and that variation in temperature within this range will have little effect on growth rate. The experimental temperatures employed in this study (20, 24, 28 and 30°C)

fall within this range, potentially explaining the lack of a significant effect of temperature on growth in this study.

RNA:DNA was significantly affected by both experimental ration and temperature. Several studies have documented the rapid response of RNA:DNA to changes in feeding and nutritional condition (Malloy & Targett 1994b, Chung et al. 1998, Stierhoff et al. 2009). RNA content fluctuates in accordance with potential for protein synthesis and subsequent growth. During early life stages, the majority of prey consumed is converted into energy for somatic growth; therefore, nucleic acid indices can provide a reliable indicator of recent feeding and potential growth in fish. Additionally, RNA:DNA in individual summer flounder (*Paralichthys dentatus* - Malloy & Targett 1994b), red drum (*Sciaenops ocellatus* – Rooker & Holt 1996) and weakfish (*Cynoscion regalis* – Stierhoff et al. 2009) has been shown to respond on the order of hours to days. Results of this study support previous observations of the quick response of RNA:DNA to recent feeding and nutritional status. Based on our findings, the response of RNA:DNA to feeding in juvenile Atlantic menhaden is equal to or less than 10 days.

The objective of the predictive growth model developed in this study was to estimate growth of field-caught individuals to quantify and compare relative habitat-specific production of juvenile menhaden. Because menhaden is a mobile, pelagic fish, estimated growth rates must be relevant to short temporal scales so that growth and subsequent production can be directly related to specific habitats and associated biotic and abiotic variables. Therefore, the temporal response of nucleic acids to changes in feeding and condition must be established to ensure the quantification of

reliable habitat-specific growth estimates. Thus, additional laboratory-based latency experiments are needed to more precisely define the rate of response of RNA:DNA to changes in feeding and other stimuli to determine the degree of temporal resolution our model provides.

The effect of temperature on RNA:DNA observed in this study has also been observed in several studies on other species of fish (Buckley 1982, Buckley et al. 1984, Caldarone et al. 2003, Caldarone 2005, Mercaldo-Allen et al. 2006). Because biochemical activity increases with increased temperature, the relationship between nucleic acids and growth is often temperature dependent. The significant effect observed in this study suggests the potential importance of including temperature in our predictive RNA:DNA-growth model for juvenile menhaden.

Relationships between RNA:DNA and growth rate in fish can be affected by size and ontogenetic changes (Buckley et al. 1999). As fish grow and develop, energy is allocated to other metabolic activities besides somatic growth, potentially providing unreliable estimates of nucleic acid-based growth rates. Therefore, caution must be exercised when applying predictive models to older or more developed individuals. This study incorporated individuals over a range of sizes corresponding to those observed during estuarine residency time of juvenile Atlantic menhaden. Pearson product moment correlation analysis did not indicate a significant relationship between body mass and any of the variables included in our model (instantaneous growth, RNA:DNA, temperature). Additionally, body mass did not meet the 0.05 significance level required for entry into the model and was therefore not included. Finally, residuals of our model plotted against body mass exhibited no

apparent trend and were randomly distributed. These findings suggest that our model can be reliably applied to individuals within the size range used in this study, and more importantly, to field-caught individuals sampled during estuarine residency.

The predictive model developed by this study can be used to estimate growth rates of juvenile Atlantic menhaden with inputs of RNA:DNA and temperature. The relatively strong relationship between these factors suggests that the model can provide a reliable method for estimating growth of field-caught individuals. Using this index, growth and subsequent production of potential estuarine nursery habitats can be quantified in order to spatially and temporally assess the quality of potential estuarine nursery habitats for this species. This information can be beneficial to managers in evaluating relative nursery habitat contribution, improving understanding of recruitment processes, and focusing management, conservation and restoration efforts for Atlantic menhaden.

Table 2.1. Summary of design of laboratory growth experiments on juvenile Atlantic menhaden. Each value in the temperature column represents an individual tank mean and standard error based on daily measurements taken over the 10 d experimental period.

Chapter 3:

**Temporal response (latency) of RNA-DNA ratio to changes
in feeding regime in juvenile Atlantic menhaden *Brevoortia
tyrannus***

Abstract

Fluorometric techniques were used to measure RNA:DNA values to evaluate the temporal response (latency) of nucleic-acid based condition to changes in feeding regime of juvenile Atlantic menhaden (*Brevoortia tyrannus*). The 20-day experiment consisted of a completely randomized design involving a fully fed control treatment and three additional treatments of varying starvation duration before reintroduction of food. Individuals were sampled at regular intervals throughout the experiment, and the time for a significant change in RNA:DNA to be observed and the rate of change following removal and reintroduction of food were determined. Following changes in feeding regime, RNA:DNA responded rapidly. After removal of food, RNA:DNA declined within 2 days, becoming significantly different from the control within 4-6 days. Following the reintroduction of food, RNA:DNA responded within 2 days; however, there was evidence of hysteresis after prolonged periods of starvation. By quantifying the temporal response of RNA:DNA in this species, reliable inferences regarding the temporal and spatial scale of nucleic-acid based estimates of condition and growth from field-collected individual can be made.

Introduction

Enhanced knowledge and understanding of growth dynamics is a priority for fisheries research and a vital component of fisheries management efforts. Increased growth rates during larval and juvenile life stages are typically associated with increased survivorship by reducing stage-duration (Houde 1987, Rice et al. 1993a, Rice et al. 1993b) and decreasing over-winter mortality of early life stages (Post & Evans 1989a, Post & Evans 1989b, Conover & Schultz 1997, Sogard 1997). Small variations in growth can lead to variation in mortality that has substantial impacts on recruitment success (Houde 1987).

Individual growth can be influenced by a range of factors including prey quality (Mazur et al. 2007), prey availability (Paperno et al. 2000, Graeb et al. 2004) and abiotic variables such as temperature, salinity and dissolved oxygen (Hettler 1976, Manderson et al. 2002, McNatt & Rice 2004). Knowledge regarding the relationships between environmental factors and growth may aid in the identification and improve our understanding of important biotic and abiotic processes regulating recruitment of fishes. For juvenile stages, these influencing factors and resultant growth rates often vary over small spatial and temporal scales, making indices of growth a frequently used metric to assess habitat quality (Sogard 1992, Meng et al. 2000, Nislow & Folt 2000, Le Pape et al. 2003, Amara et al. 2007, Glass et al. 2008). Moreover, it has been proposed that the relative value of a potential nursery habitat is determined by the contribution individuals residing in the habitat make to the ultimate level of recruitment (Beck et al. 2001). Because this contribution is a function of both the size and number of individuals surviving to adulthood (Beck et al. 2001),

growth rate estimates can be coupled with site-specific abundance to quantify relative habitat production in order to evaluate juvenile nursery habitats and identify relationships to environmental variables.

Due to the dynamic nature of aquatic environments and the vagility of juveniles of many fishes, measures of growth must be determined at fine spatial and temporal scales if environmental conditions observed at the time of sampling events are to be reliably associated to growth rates in specific habitats. To achieve this objective, the technique used to estimate growth must have a temporal resolution sufficiently small to provide information only on the growth achieved during recent habitat residency. The technique must also respond to the temporal variability of the environmental conditions in the habitat. Few conventional methods of estimating growth meet these standards. Caging studies have been used extensively to obtain information on growth rates of fishes (Duffy-Anderson & Able 1999, Phelan et al. 2000, Kellison et al. 2003). However, this technique prevents the natural movement of individuals into areas that would otherwise produce different rates of growth (Phelan et al. 2000), thereby potentially biasing estimates. Mark-recapture, size-at-age approaches to estimating growth integrate past growth over extended time periods and hence likely, multiple habitats and environmental conditions. Otolith-based growth estimates may be unsuitable for this application because of the potential lagged response of between somatic and otolith growth rates (Neilson & Geen 1985, Molony & Choat 1990, Rooker & Holt 1997). Furthermore, somatic and otolith growth can become uncoupled during periods of slow growth (Secor & Dean 1989,

Szedlmayer 1998). These two features of otolith-based approaches make them potentially unsuitable for this application.

Biochemical estimates are considered to be the most sensitive and effective means of estimating recent growth of larval and juvenile fish because of the rapid response at the cellular level to changes in external conditions (Robinson & Ware 1988, Ferron & Leggett 1994, Theilacker & Shen 2001). In particular, nucleic acid-based indices have been used extensively to estimate recent growth (Chapter 2 and Bulow 1970, Buckley 1982, Buckley 1984, Bulow 1987, Foster et al. 1993, Malloy & Targett 1994a, Malloy et al. 1996, Rooker & Holt 1996, Caldarone 2005, Mercaldo-Allen et al. 2006, Mercaldo-Allen et al. 2008). Nucleic acid-based approaches have also been used to quantify the relative health or condition of larval and juvenile fishes (Buckley 1980, Wright & Martin 1985, Clemmesen 1987, Kimura et al. 2000, Fukuda et al. 2001, Kono et al. 2003). The ratio of RNA to DNA is often found to be the most sensitive indicator of changes in recent feeding and growth (Buckley 1979, Clemmesen 1987, Canino 1994, Suneetha et al. 1999, Catalan et al. 2007). The amount of DNA, remains relatively constant per cell and is a characteristic of individual species. Changes in DNA levels are indicative of changes in cell number. In contrast, RNA content fluctuates in response to ribosomal numbers and the level of protein synthesis (Bulow 1970, Buckley et al. 1984, Ferron & Leggett 1994). Therefore, the ratio of RNA to DNA levels provides a standardized measure of the protein synthetic capacity of cells, with higher RNA:DNA values suggesting increased potential for growth and enhanced condition.

Nucleic acids, particularly RNA:DNA values have been shown to respond to changes in feeding and condition on the order of hours to days (Wright & Martin 1985, Bulow 1987, Malloy & Targett 1994b, Arndt et al. 1996, Kono et al. 2003, Catalan et al. 2007). The rapid response of RNA:DNA can provide valuable information on spatial and temporal scales relevant to conditions at the time of sampling, allowing investigation of the relationship between biotic and abiotic factors and the variability in growth of larval and juvenile fishes. However, the temporal response of nucleic acid-based indices may be species-specific and often varies as a result of multiple factors including ontogenetic stage (Richard et al. 1991, Rooker & Holt 1996), feeding regime (Johnson et al. 2002), and temperature (Kono et al. 2003). If the assumption of rapid response is incorrect, inferred linkages between growth rates and environmental variables may be erroneous. Additionally, without determination of the temporal response of a measured nucleic acid parameter, neither the temporal nor spatial scale of index-based, habitat-specific growth estimates can be established. Therefore, quantification of the temporal response of a selected nucleic acid parameter to a change in condition is necessary to reliably apply a nucleic acid-based growth index to field caught individuals.

One species that may benefit from an enhanced understanding of relationships with the environment is Atlantic menhaden (*Brevoortia tyrannus*, hereafter menhaden). Menhaden is a highly abundant, obligate filter-feeding planktivore frequently occurring in dense schools ranging from Nova Scotia to central Florida. Ecologically, menhaden is a filter feeder (Durbin & Durbin 1975, Peters & Schaaf 1981, Lewis & Peters 1984, Friedland et al. 2006) and represent an important dietary

component for many species of fish (Sykes & Manooch 1979, Hartman & Brandt 1995, Overton et al. 2008), birds (Spitzer 1989) and marine mammals (Hildebrand 1963). Menhaden, therefore, occupy a central position in estuarine and coastal ecosystems (Baird & Ulanowicz 1989). Economically, this species supports valuable commercial reduction and bait industries (Ahrenholz et al. 1987).

Adult menhaden spawn in the coastal ocean. Larvae are transported to estuarine environments (Quinlan et al. 1999) where juveniles reside during their first year of life. Juvenile abundance indices for the Chesapeake Bay have declined since the 1970s (ASMFC 2006). The cause for the observed decline is uncertain. The adult stock is purportedly healthy (ASMFC 2006). Hypotheses related to changes in the adult age structure and oceanographic climate have been proposed (ASMFC 2004). Quinlan & Crowder (1999) identified processes occurring during the juvenile stage, coinciding with estuarine-residence as being the life history stage that is most important to determining population growth. Thus, it has also been hypothesized that poor juvenile growth and survival may account for the observed decline in the recruitment indices. Therefore, information regarding the growth and survival dynamics of estuarine-resident menhaden may be valuable to understand recruitment patterns and developing effective management strategies. To this end, in Chapter 2, I developed a predictive RNA:DNA-based index to estimate growth of field-caught menhaden. These growth estimates can be coupled with abundance data from fishery independent surveys to quantify and compare habitat-specific production of potential menhaden nursery habitats, and ultimately evaluate the abiotic and biotic factors influencing estuarine productivity dynamics for this species. However, to reliably

relate growth rate estimates to site-specific habitat residency and associated environmental factors, knowledge of the temporal response of RNA:DNA to changes in nutritional condition is required. Here, I report on laboratory experiments that investigated the temporal sensitivity of RNA:DNA in juvenile menhaden by quantifying the latency of RNA:DNA estimates to changes in feeding regime. The results of this study will help determine the temporal and spatial scales at which the previously developed RNA:DNA-based growth index can be applicable.

Materials and Methods

Latency experiments

The laboratory experiment was conducted using young-of-the-year, juvenile menhaden collected by beach seine from littoral habitats in the Patuxent River, MD. Fish were held for at least seven days in holding tanks to allow recovery from transportation and handling-induced stress, and acclimated to the experimental conditions for at least fourteen additional days before being used in experiments. During this period, fish were fed *ad libitum* pelleted food hourly, nine times daily (Zeigler Finfish Starter Meal, Gardners, PA, 0.42- 0.595 mm). Individual fish showing signs of injury or disease were not used in the experiments. A photoperiod of 14 hr light – 10 hr dark was employed throughout all phases of the work.

The temporal response experiment was conducted at 24°C over a period of 20 days from July 25 - August 14, 2008. The experiment was conducted as a completely randomized design involving four starvation period treatments of different duration. Experimental treatments consisted of a control fed *ad libitum* throughout the duration of the experiment and three starved/refed treatments. Each treatment was replicated

three times. All treatment groups had received consistent rations prior to use in the experiment to limit variation in initial RNA:DNA concentrations. To begin the experiment, 45 fish from the common stock tank were randomly assigned to each experimental tank. Subsequently, fish in fed treatments were fed nine times daily at the amount calculated to give a ration of 11% body weight.d⁻¹.fish⁻¹. Based on preliminary experiments and observations, this ration is above maintenance and close to *ad libitum*. At the beginning of the experiment fish in all tanks except those in the control treatment (0S – 20F) were starved. The refeeding treatments commenced after 2 (2S – 18F), 4 (4S – 16F), and 8 (8S – 12F) days. A sample of fish (n=5) was removed from each tank on days 0, 2, 4, 6, 8, 10, 12, 16 and 20. Subsequently, ration was adjusted to maintain a constant 11% body weight.d⁻¹.fish⁻¹. Immediately after sampling, each fish was euthanized, measured, weighed and stored at -80°C for subsequent biochemical analysis.

Fish used in the experiments ranged from 7.8 – 22.5g. The experiment used 12 circular, 511-l fiberglass tanks. Each tank was provided with flow through water from the Patuxent River. Because menhaden is a planktonic filter-feeder, serial filtration (10, 5 and 1 µm) of inflowing water was utilized to ensure reliable ration treatments were maintained. Water quality was monitored regularly and all tanks were maintained at 24°C throughout the experiment.

Biochemical analyses

The RNA:DNA levels of menhaden sampled during the experiment were analyzed following the protocol described in Chapter 2. I verified that sample degradation does not occur as a result of storage at -80C. Briefly, epaxial muscle was

dissected from individual fish and the RNA and DNA content of these muscle samples were quantified using the 1 dye/2 enzyme microplate fluorometric assay. Triplicate samples of muscle from each fish were analyzed in a random order. RNA:DNA values were calculated based on calibration curves developed for each microplate. Calibration relationships never explained less than 99% of the variation in the data.

Statistical analyses

Tank mean RNA:DNA levels were calculated from the mean of individual fish samples taken from each tank on each sampling day. Tank means were considered as replicates for each time point. Tukey's HSD tests were employed to determine the time point at which treatments became significantly different from the control (0S – 20F) after the onset of starvation and following reintroduction of food. To determine the rate of change of RNA:DNA to different periods of starvation, Fisher's LSD test was used to compare regression coefficients between treatments from the onset of starvation until either feeding was resumed or values became significantly different from the control treatment (0S – 20F). Similarly, regression coefficients were compared from the reintroduction of food until RNA:DNA values were no longer significantly different from the control treatment (0S – 20F).

Results

Response of RNA:DNA corresponded to changes in feeding conditions in juvenile Atlantic menhaden. Fish fed constantly throughout the 20 day experiment (0S -20F) maintained consistent RNA:DNA values until day 20 when values became

significantly lower from those observed on day 0 (Figure 3.1, $p = 0.03$). The 2S – 18F treatment mean RNA:DNA decreased from 5.63 ± 0.59 (mean \pm S.E.) to 4.14 ± 0.05 (a 26.5 % reduction) after 2 days of starvation. The tank mean RNA:DNA subsequently increased to 4.96 ± 0.10 (19.8 % increase) by day 4 following refeeding (Figure 3.1 - A). However, RNA:DNA in the 2S – 18F treatment did not differ significantly from the 0S – 20F treatment during the experiment. In contrast significant differences between treatment and control RNA:DNA values were observed in the other treatments. During the 4d starvation treatment (4S-16F treatment), average RNA:DNA levels declined from 6.07 ± 0.52 (mean \pm S.E.) to 3.77 ± 0.13 (a 37.9 % reduction) after 4 days of starvation (Figure 3.1 - B, $p = 0.03$). Following refeeding, the 4S – 16F treatment mean RNA:DNA increased to 4.69 ± 0.24 by day 6 (a 24.4 % increase) and was no longer significantly different from the control (Figure 3.1 - B). During the 8d starvation treatment (8S-12F), average RNA:DNA levels declined from 6.49 ± 0.49 (mean \pm S.E.) to 3.45 ± 0.14 (a 46.8 % reduction) after 8 days of starvation (Figure 3.1 – C). Treatment RNA:DNA values were significantly different from the control after 6 days ($p = 0.01$). Following refeeding, the 8S – 12F treatment mean RNA:DNA increased to 4.74 ± 0.56 by day 16 (a 37.4 % increase) and was no longer significantly different from the control (Figure 3.1 – C).

RNA:DNA appeared to be a more sensitive index of feeding condition in juvenile menhaden than either RNA content or DNA content (Figure 3.2). Periods of starvation were characterized by a general decrease in RNA content and a concomitant increase in DNA content. Likewise, following refeeding, RNA content

increased while DNA content generally declined. These joint fluctuations of RNA and DNA content in response to periods of starvation and refeeding amplified the RNA:DNA signal in this study, making this measure most responsive to changes in feeding condition.

The rate of change of RNA:DNA to changes in feeding condition did not differ significantly between treatments. Regression coefficients describing the rate of decline of RNA:DNA from the onset of starvation until the point of significant difference from the control treatment (0S – 20F) of -0.745, -0.574 and -0.451 were estimated for treatments 2S – 18F, 4S – 16F and 8S – 12F, respectively, (Figure 3.3). Regression coefficients describing the decline in RNA-DNA ratios among treatments did not differ significantly during periods of starvation in juvenile Atlantic menhaden. However, there was a tendency for slopes describing the response to longer starvation periods to be less steep than those describing shorter starvation periods. Likewise, regression coefficients of 0.407, 0.460 and 0.168 were observed for treatments 2S – 18F, 4S – 16F and 8S – 12F, respectively, from the reintroduction of food until RNA:DNA values were statistically indistinguishable from the control (0S-20F) treatment (Figure 3.4). The regression coefficients describing change in RNA:DNA to reintroduction of food did not differ significantly among treatments. Data describing recovery following 2 and 4 d of starvation were more similar than those describing recovery from the longer 8 d starvation period, and are suggestive of hysteresis in RNA:DNA levels.

Discussion

My results show that RNA:DNA responds rapidly to changes in feeding condition in juvenile Atlantic menhaden, supporting the utility of this index to quantify recent growth conditions for menhaden in the field. When food was removed, RNA:DNA values in all treatments declined by the next sampling period (2 days), suggesting a rapid response to changes in feeding conditions and the consequent response of RNA:DNA levels. When compared to those fish held under approximately *ad libitum* feeding conditions, statistically significant changes in RNA:DNA were detectable within 4 days of starvation. Though the overall rate of decrease in RNA:DNA slowed with increased starvation duration, potentially due to an RNA:DNA threshold under starvation conditions, the rates of decline of RNA:DNA did not differ significantly among starvation treatments. Equally, when food was reintroduced, RNA:DNA levels exhibited increases by the following sampling period (2 days) in treatments starved for only 2 and 4 days, becoming statistically indistinguishable from the control treatment. However, fish subjected to 8 days starvation required 6 days to exhibit increased RNA:DNA, suggesting a potential carry-over i.e., hysteresis effect to an extended period of starvation. However, regardless of starvation duration, RNA:DNA values eventually recovered to and were statistically indistinguishable from control values following the reintroduction of food in juvenile Atlantic menhaden.

An improved understanding and quantification of the temporal response (latency) of a selected condition or growth index is critical to obtaining accurate data regarding fish growth and to reliably evaluating relationships between growth and

environmental conditions in specific habitats at the time of sampling events (Ferron & Leggett 1994, Arndt et al. 1996, Buckley et al. 1999, Caldarone 2005). In their review of indices of growth and condition in fish, Ferron & Leggett (1994) identified three attributes of a “good” index: reliability, sensitivity and latency. They define reliability of an index as a measure of its accuracy and repeatability. I have shown previously that RNA:DNA is a reliable growth index for menhaden (Chapter 2). The results of Chapter 2 with regard to the high precision of the analyses also indicates that RNA:DNA is likely to be a sensitive growth index. Indeed, nucleic acid-based indices have been found to be among the most sensitive measures of recent growth, condition and feeding in larval and juvenile fish (Bulow 1970, Buckley 1979, Buckley 1980, Buckley 1984, Wright & Martin 1985, Fukuda et al. 1986, Bulow 1987, Clemmesen 1987, Robinson & Ware 1988, Ferron & Leggett 1994, Clemmesen 1994, Clemmesen & Doan 1996, Buckley et al., 1999). The experiment reported herein sought to evaluate the latency of the RNA:DNA index. Ferron & Leggett (1994) defined latency as the time required for a given change in food availability to be reflected as a significant change in the index of condition used. Because fish in the natural environment typically experience fluctuations in food availability occurring on short temporal scales, indices characterized by the shortest latency are of most utility to field studies (McLaughlin et al. 1995, Suneetha et al. 1999).

Many studies have investigated the response of nucleic acid-based measures to changes in feeding regime (Buckley 1979, Wright & Martin 1985, Jurss et al. 1986, Bastrop et al. 1991, Richard et al. 1991, Clemmesen 1994, McLaughlin et al. 1995, Arndt et al. 1996, Chung et al. 1998, Gwak & Tanaka 2001, Johnson et al. 2002,

Caldarone 2005). Studies that compared different nucleic acid-based indices have established RNA:DNA as the most responsive (Clemmesen 1987, Canino 1994, Suneetha et al. 1999, Catalan et al. 2007). My findings of a significant change in RNA:DNA within four days in response to either initiation of starvation or reintroduction of food falls within the range of previous results found in other studies (Wright & Martin 1985, Clemmesen 1987, Mugiya & Oka 1991, Canino 1994, Clemmesen 1994, Rooker & Holt 1996, Stuck et al. 1996, Suneetha et al. 1999, Kimura et al. 2000, Vidal et al. 2006, Catalan et al. 2007, Stierhoff et al. 2009). Further work is required to quantify the temporal response of RNA:DNA in juvenile menhaden at even shorter time scales, as some research has established changes in RNA:DNA within hours of a change in feeding regime (Wright & Martin 1985).

The decreases in RNA:DNA observed in response to starvation were produced by immediate reductions in RNA content and accompanied by a slight increase in DNA content under starved conditions, similar to results found in previous studies (Buckley 1979, Stuck et al. 1996, Chung et al. 1998, Suneetha et al. 1999, Gwak & Tanaka 2001). Starvation typically results in degradation of all types of RNA and often a concomitant increase in DNA content per unit tissue weight. The observed increase in DNA is the result of an increased number of cells per unit tissue caused by catabolism of intracellular constituents, reduction of cytoplasmic volume and decreased cell weight under starved conditions (Mustafa & Mittal 1982). After reintroduction of food, pre-starvation cellular conditions are restored, resulting in larger cells per unit tissue mass and subsequent decline in DNA concentration (Mustafa & Mittal. 1982). The apparent conservation of DNA under periods of stress

in fish allows for RNA measurements to be standardized to cell number, making measurements of RNA:DNA highly sensitive to starvation conditions (Buckley et al. 1999).

The relatively immediate response of RNA content to changes in feeding supports the utility of our RNA:DNA-based growth index to detect recent changes in growth and condition in juvenile menhaden. Several studies have observed a considerable lag between changes in short-term feeding regime and the response of RNA content. These studies indicate that changes in rates of protein synthesis precede changes in RNA concentration (Loughna & Goldspink 1984, McMillan & Houlihan 1988). Because changes in protein synthesis occur in response to changes in both the number of ribosomes and in the activity of those ribosomes (Young 1970, Henshaw et al. 1971, Loughna & Goldspink 1984), these findings have been attributed to changes in ribosomal activity as opposed to increases or decreases in RNA concentration. My results are contrary to these findings, showing no substantial delayed response time.

Statistical comparison of the rates of change of RNA:DNA in response to changes in feeding conditions detected no significant differences among treatments. However, the rate of decline decreased with increasing starvation duration. This diminishing rate of decline may be attributable to RNA:DNA levels approaching a lower limit, or threshold value during prolonged periods of starvation, as RNA:DNA levels of fish starved for 8 days appeared to stabilize. The juvenile menhaden in this study exhibited a mean basal RNA:DNA ≈ 3.5 after three days of food deprivation. Similarly, Mugiya & Oka (1991) observed RNA:DNA values maintained at a basal

level after 3 days starvation in rainbow trout *Oncorhynchus mykiss*. After the reintroduction of food, menhaden starved for 2 and 4 days showed immediate increases in RNA:DNA values by the next sampling period. RNA:DNA values of menhaden starved for 8 days, however, did not respond as rapidly. The rate of change of the 8S – 12F treatment following refeeding, although statistically similar, was reduced compared to fish starved for lesser time periods, suggesting the temporal response of RNA:DNA in juvenile menhaden may decline after prolonged periods of starvation or exposure to other stressors. Additionally, although RNA:DNA values of treatments 2S - 18F and 4S – 16F became statistically indistinguishable from the control treatment only 2 days following refeeding, RNA:DNA levels of starved treatments remained below that of the control until day 16, at which point RNA:DNA levels of the control had declined, possibly for reasons described below.

I did not find evidence of a compensatory response of RNA:DNA to changes in ration, as has been shown in other research (Miglavs & Jobling 1989, Malloy & Targett 1994a, Catalan et al. 2007). Following refeeding, Malloy & Targett (1994a) observed RNA:DNA values increase to levels above those observed prior to starvation in summer flounder. Furthermore, Catalan et al. (2007) found that the response of RNA:DNA following reintroduction of food was positively related to the duration of starvation. Miglavs & Jobling (1989) attribute the compensatory response to hyperphagic feeding or enhanced conversion efficiency following reintroduction of food after a period of malnourishment. It is conceivable that my method of feeding during the experiment prohibited menhaden from acquiring food at elevated levels required to produce a compensatory response. Because menhaden obtain food by

filtering particles from the water column, coupled with the sinking nature of the fish meal used in my study, fish would have to ingest sufficient quantities of food before it sank to the floor of the experimental tank, where it would become unavailable to the menhaden. I attempted to counteract this limitation by feeding nine times throughout the day; however, it is possible that individuals may not have been able to take full advantage of all food offered. Alternatively, the decreased response of RNA:DNA after starvation may be due to an inefficiency to ingest food or convert to required energy after a period of decreased food intake. Perhaps juvenile menhaden require a period of acclimation to return to levels of feeding and conversion efficiency maintained prior to undernourishment. Regardless, the rate of response of RNA:DNA in juvenile menhaden following reintroduction of food appears to be dependent upon the duration of the food deprivation.

RNA:DNA values of fish subjected to the control treatment (0S – 20F) remained relatively consistent until day 16 when they began to decline. In comparison to values observed on day 0, RNA:DNA became significantly different on day 20. I expected that under *ad libitum* feeding conditions, RNA:DNA values should have remained constant throughout the experiment. There are several possible explanations. I believe that the periodic removal of individuals from experimental tanks during each sampling period may have been responsible for the observed declines in RNA:DNA near the end of the experiment. As mentioned, at each sampling period five individuals were removed for biochemical analysis from each experimental tank. Therefore, by day 16, only 5 – 10 fish remained in each tank. Menhaden is a schooling species and prefers to congregate in aggregations. The low

number of individuals in each tank compared to earlier in the experiment may have imposed stress on remaining individuals, ultimately lowering RNA:DNA. Similarly, with fewer individuals composing schools within a tank, the time required to detect food was likely slower, and competition for food between individuals lower by the end of the experiment. Potentially slower recognition of food and/or decreased feeding rates may have contributed to decreased ingestion of food before particles sank to the floor of the tank, becoming unavailable for consumption. Additionally, as fish were removed for subsequent analysis, food was supplied to the tanks in proportion to the weight of remaining individuals. Thus lower concentrations of food were added over the course of the experiment. However, the size of the experimental tanks remained constant. Therefore, as the experiment progressed, fewer individuals were required to search the same volume of water to encounter lower concentrations of food. Durbin & Durbin (1983) found a direct relationship between menhaden swimming speed and the concentration of plankton in the environment. Therefore, individuals remaining by day 16 were likely swimming more slowly, consuming less food, which contributed to a lower positive energy balance (Macy et al. 1990), and decreased RNA:DNA values. It is possible that any of these factors or a combination may have contributed to the decline in RNA:DNA seen in the control treatment by the end of the experiment.

This study represents the first examination of the latency of RNA:DNA in response to changes in ration in juvenile Atlantic menhaden. Although my results support the ability of RNA:DNA to detect short-term changes in condition and hence, provide a means of measuring growth potential on recent time scales, further research

is desired to more comprehensively describe the temporal dynamics of RNA:DNA in this species. Investigation of several factors and their relationship to the utility of RNA-DNA ratios in menhaden is warranted.

My study was conducted at 24°C. This temperature was chosen to reflect the median temperature experienced by juvenile menhaden during estuarine residence in Chesapeake and Delaware Bays. Had experiments been conducted at temperatures above or below this level, potentially different results regarding the response time of RNA:DNA may have resulted. Further experimentation on the response of RNA:DNA at different thermal regimes is required for full elucidation of RNA:DNA-temperature dynamics. Relationships between RNA:DNA and growth rate have been found to be temperature dependent in several studies (Buckley 1982, Buckley et al. 1984, Caldarone et al. 2003, Caldarone 2005, Mercaldo-Allen et al. 2006) and specifically in juvenile Atlantic menhaden (Chapter 2). Typically, as temperature increases, lower RNA:DNA values are associated with increased rates of growth. This has been attributed to a compensatory mechanism of increasing ribosomal numbers at lower temperatures (Goolish et al. 1984, Houlihan 1991). Suneetha et al. (1999) and Kono et al. (2003) observed higher responsiveness of RNA:DNA to starvation at increased temperatures, and Jurss et al. (1987) noted higher RNA:DNA in both fed and starved fish at lower temperatures. Conversely, in response to changes in feeding conditions, RNA:DNA changed more rapidly at lower temperatures in juvenile summer flounder (Malloy & Targett 1994a). The observed unpredictability in the response of RNA:DNA to variable temperatures requires the quantification of the temporal response over a range of potential thermal scenarios.

Because juvenile Atlantic menhaden will experience a range of thermal conditions during estuarine residence time, a thorough understanding of the effect of temperature on the temporal response of RNA:DNA is required to obtain reliable nucleic acid-based estimates of growth in the field. Together, these studies indicate that the temperature-dependence of the sensitivity and latency of RNA:DNA indices (sensu Ferron & Leggett) remains undescribed.

Similarly, the response of RNA:DNA to feeding conditions and other factors is often dependent upon size and ontogenetic stage (Buckley et al. 1999). Throughout growth and development, energy will be allocated to various metabolic pathways and as such, the response of RNA:DNA may be variable during different life history stages. The predictive RNA:DNA-growth model developed in Chapter 2 was intended for juvenile menhaden, approximately 35 – 140 mm TL, residing in estuarine habitats during their first year of life. Individuals in this study were 90 – 129 mm TL; and therefore, do not fully encompass the range of sizes present during estuarine residency. The response of growth and RNA:DNA to starvation and other stressors is likely different between menhaden of different size classes. For example, larger individuals found later in the growing season may possess enhanced energy reserves that serve to dampen the negative effects of starvation, thereby lessening observed declines in RNA:DNA levels. Rooker & Holt (1996) found that RNA:DNA in red drum was less responsive to starvation with increasing age. Conversely, smaller menhaden collected shortly following ingress will likely possess greater growth potential than larger individuals found later in the season, and therefore exhibit a greater range of RNA:DNA in response to feeding and growth conditions.

To fully understand the temporal response dynamics of juvenile menhaden throughout growth and development, further experimentation should be conducted which expands the size range of experimental individuals to that which is found in the estuarine environment during their first year of life. By quantifying the temporal response dynamics over all size ranges of estuarine-dependent individuals, more reliable associations can be determined between RNA:DNA, growth and environmental factors observed at the time of sampling events.

This study quantified the responsiveness of RNA:DNA to the abrupt change in feeding from *ad libitum* to starvation conditions. However, in the natural environment changes in feeding regime are likely less drastic, and as such, the response of RNA:DNA less pronounced. Therefore, quantification of the temporal sensitivity to intermediate changes in feeding is desired to ensure reliable estimates of growth and condition in the field. For instance, Johnson et al. (2002) observed that intermediate feeding levels maintained relatively constant RNA:DNA levels, suggesting that this biochemical measure may be unable to detect subtle changes in feeding condition in the wild. Elucidation of such detection limits is necessary to make reliable inferences regarding the condition and growth of field-caught individuals. Further experimentation including treatments of intermediate feeding similar to Wright & Martin (1985), Arndt et al. (1996) and Johnson et al. (2002) may help to fully characterize the temporal response of RNA:DNA to realistic changes in feeding and growth conditions in juvenile Atlantic menhaden.

Quantification of the temporal response of any laboratory-derived index is a necessary prerequisite to the field application of a selected parameter as a measure of

growth or condition. The results of the present study suggest that RNA:DNA provides a highly sensitive measure of recent feeding, and thus a reliable measure of potential growth in juvenile Atlantic menhaden. The description of the temporal dynamics of RNA:DNA obtained from this study will allow valid inferences to be made regarding RNA:DNA, growth and their relationships to specific habitats and environmental variables.

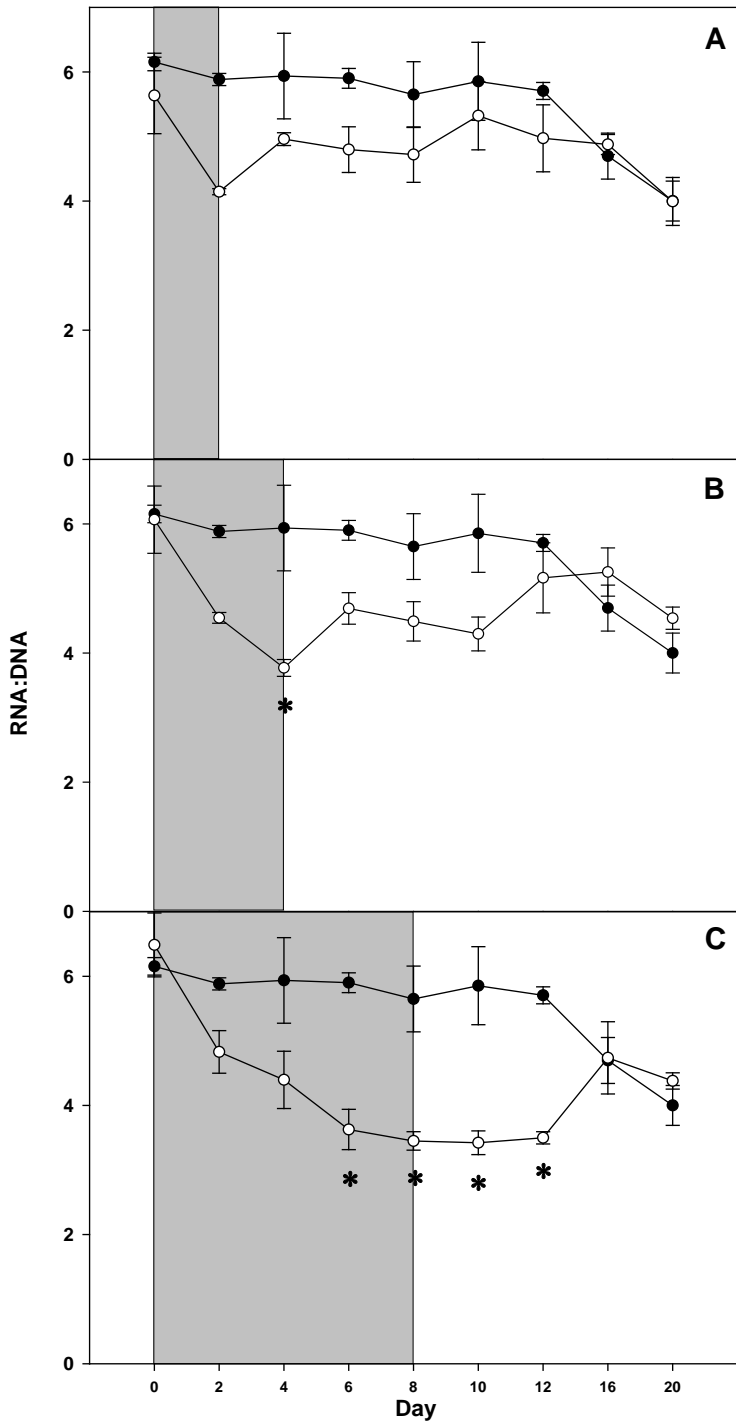

Figure 3.1. Response of RNA:DNA to changes in feeding condition in juvenile Atlantic menhaden. Treatment mean RNA:DNA (\pm S.E.) in continuously fed control treatment (closed circles) compared to starved/refed treatments (open circles): A) 2S – 18F, B) 4S – 16F and C) 8S – 12F. Shaded area represents period of starvation. Significant differences in RNA:DNA between treatment and control at a given sampling event represented by asterisks

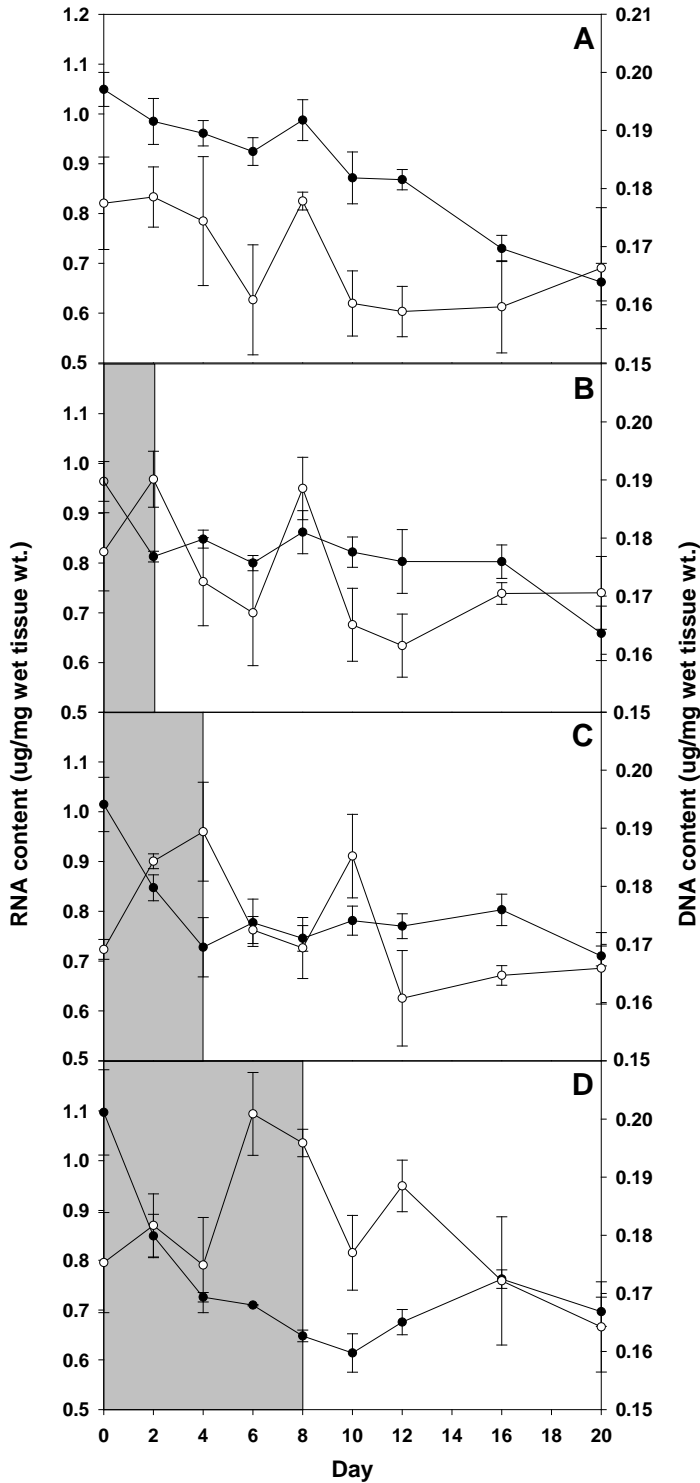

Figure 3.2. Response of RNA content (closed circles) and DNA content (open circles) to changes in feeding condition in juvenile Atlantic menhaden. Treatment mean RNA and DNA content (\pm S.E.) in A) control, B) 2S – 18F, C) 4S – 16F and D) 8S – 12F treatments. Shaded area represents period of starvation.

Figure 3.3. Regression of experimental treatments from the onset of starvation until either feeding was resumed (2S – 18F) or RNA:DNA values became significantly different from the control. Regression lines for the 2S – 18F (solid), 4S – 16F (dashed) and 8S – 12F (dotted) treatments shown.

Figure 3.4. Regression of experimental treatments from the reintroduction of food until RNA:DNA values were no longer significantly different from the control. Regression lines for the 2S – 18F (solid), 4S – 16F (dashed) and 8S – 12F (dotted) treatments shown.

Chapter 4:

**A preliminary assessment of broad- and fine-scale patterns
in RNA:DNA-based growth, abundance and production of
juvenile Atlantic menhaden in the Chesapeake and
Delaware Bays**

Abstract

RNA:DNA-based estimates of instantaneous growth in the field were combined with site-specific abundance estimates to calculate the production of habitats within the Chesapeake and Delaware Bay estuaries. High spatiotemporal variability characterized both broad-scale (system-level) and fine-scale (site-level) estimates of growth, abundance and production. Z-scores indicated specific sites that exhibited growth consistently above- or below-average within years in both 2007 and 2008; however, the high frequency of zero hauls generally dampened potential site-specific differences in abundance and production. These results suggest specific sites do not provide sufficient consistency to be classified as nurseries, but rather juvenile menhaden utilize a mosaic of sites within estuaries to promote growth, survival and production. Therefore, designation of essential fish habitat for the purposes of conservation and restoration may prove difficult; however, the identification of environmental variables related to observed patterns in site-specific production may provide valuable insight for the management of this species.

Introduction

Many fish species utilize estuarine nursery habitats during early-life stages (June & Chamberlain 1959, Weinstein 1979, Nixon 1980, Hoss & Thayer 1993, Able & Fahay 1998, Able 1999, Minello et al. 2003). Estuaries offer a variety of habitat types for shelter and protection from predators, and provide favorable physicochemical conditions and prey resources. These attributes, along with the highly productive nature of the estuarine environment, make nursery habitats critical to the growth and survival of estuarine-dependent fish species (Miller et al. 1985, Beck et al. 2001). However, the productivity of nursery habitats is generally not homogenous within or among estuaries. Beck et al (2001) define a habitat as a nursery if it produces disproportionately more recruits per unit area than do other habitats. The number of recruits that a nursery habitat contributes to the population is controlled by factors that vary both spatially and temporally (Manderson et al. 2002). Identifying which factors influence the relative production of nursery habitats and how these factors vary over space and time will increase our understanding of population dynamics and recruitment, and aid in the design and assessment of management efforts for estuarine fishes.

A recent priority of fisheries management is the designation of essential fish habitat (EFH), defined by the Magnuson-Stevens Act as *those waters and substrates necessary to fish for spawning, breeding, feeding, or growth to maturity* (NOAA 2007). The criteria used to classify areas as EFH require site-specific information regarding abundance, growth, survival and production, all of which can be used to assess the relative contribution of nursery habitats. The abundance of individuals

within a habitat may provide valuable information regarding the ability of a habitat to serve as EFH for a specific species. However, these data alone cannot reliably be used to estimate the contribution of a specific habitat, because it is often uncertain as to whether or not individuals residing in a particular habitat will survive to adulthood (Beck et al. 2001). Because fish growth rates are generally positively associated with survival, estimates of growth when combined with habitat-specific abundances can provide an indicator of habitat quality (Sogard 1992, Meng et al. 2000, Nislow & Folt 2000, Le Pape et al. 2003, Amara et al. 2007, Glass et al. 2008). Rapid growth is thought to increase the probability of survival in larval and juvenile fishes by decreasing the time spent in size-selective predation ranges (reduced stage-duration) and lowering over-winter mortality rates (Houde 1987, Miller et al. 1988, Post & Evans 1989a, Post & Evans 1989b, Rice et al. 1993a, Rice et al. 1993b, Conover & Schultz 1997, Sogard 1997, Grant & Tonn 2002, Huss et al. 2008). Beck et al. (2001) describe the contribution of a habitat as a function of both the size and number of individuals recruiting to the adult spawning population. Therefore, the quantification of nursery habitat production requires data regarding site-specific abundance and growth rates of individuals. Coupling these values will generate a site-specific production estimate which can be used to assess relative habitat contribution and identify potential factors influencing variability in nursery habitat contribution.

Although reliable site-specific abundance estimates can usually be acquired without difficulty, growth rate estimates on the same spatial and temporal scales are more difficult to obtain. Established techniques for estimating growth such as size-at-age and otolith-based measures are retrospective, and may integrate past growth over

multiple habitats, particularly in relatively mobile fish species. These growth estimation methods may provide unreliable estimates due to the potential lagged response of otolith growth to short term somatic growth rates (Neilson & Geen 1985, Molony & Choat 1990, Rooker & Holt 1997). Additionally, correlations between incremental growth of otoliths and short term somatic growth rates can become dissociated or uncoupled, particularly during periods of reduced growth (Secor & Dean 1989, Szedlmayer 1998). For example, Ahrenholz et al. 1995 reported that deposition of otolith growth increments in Atlantic menhaden (*Brevoortia tyrannus*) was less than daily at growth rates less than 0.3 mm. d^{-1} , making predictions of somatic growth from increment width potentially unreliable. These limitations reveal the need for a measure of growth that responds on the same spatial and temporal scale as respective site-specific abundance estimates.

Nucleic acid-based growth indices represent a reliable tool for estimating recent somatic growth in relation to specific habitat residence. Nucleic acid-based measures have been shown to respond to recent feeding and growth of larval and juvenile fish (Chapters 2 and 3, and see also Wright & Martin 1985, Malloy & Targett 1994a, Rooker & Holt 1996, Suthers et al. 1996, Smith & Buckley 2003). In early life stages, a major proportion of consumed energy is allocated to somatic growth (Houde & Zastrow 1993). Because ribonucleic acid (RNA) content fluctuates in response to the amount of protein synthetic machinery and ribosomal activity, it represents an indirect measure of feeding and growth rate (Bulow 1970, Buckley et al. 1984, Ferron & Leggett 1994). In contrast, deoxyribonucleic acid (DNA) content within cells remains relatively constant. Thus, RNA can be normalized with DNA

(RNA:DNA) to account for changes in cell number to yield a growth index. These nucleic acid measures respond rapidly, on the order of hours to days (Foster et al. 1993, Malloy & Targett 1994b, Rooker & Holt 1996, Stierhoff et al. 2009), providing a recent measure of condition and growth, corresponding to habitat specific abundance estimates and environmental conditions (Buckley 1984, Bulow 1987, Ferron & Leggett 1994, Buckley et al. 1999). Because estuarine environments exhibit small-scale spatial and temporal variability, the rapid response of nucleic acid-based growth indices can provide a valuable tool for evaluating growth and production of nursery habitats and associated abiotic factors.

Atlantic menhaden (*Brevoortia tyrannus* – hereafter menhaden) is considered an important species both ecologically and economically to the mid-Atlantic ecosystem. Ecologically, menhaden functions as a planktivorous filter feeder. Its dense schools can filter large amounts of plankton and organic detritus, potentially improving water quality (Durbin & Durbin 1998). Menhaden also serve as an important forage species to many piscivores such as striped bass, weakfish and bluefish, representing an important trophic link between primary production and higher trophic levels (Baird & Ulanowicz 1989). Economically, menhaden supports valuable commercial reduction and bait industries along the Atlantic coast.

Menhaden spawns predominantly in coastal ocean environments and larvae are transported to estuarine nursery habitats (Quinlan et al. 1999) where they grow and develop during their first year of life (Ahrenholz 1991). Since the 1970s, juvenile menhaden have experienced declines, as indicated by coastwide juvenile abundance indices (ASMFC 2006). In particular, declines in the Chesapeake Bay may be a

result of reduced survival of early-life stages during estuarine residency (ASMFC 2004). Quinlan & Crowder (1999) identified survival during those early life stages corresponding to periods of estuarine residence as the most important in determining population growth rates of Atlantic menhaden. The ASMFC (2004) identified estuarine habitats as those most critical to menhaden development and survival, as well as most vulnerable to anthropogenic alteration. Both the quantity and quality of estuarine menhaden habitat may have been altered by increased development and consequent increases in nutrient and chemical pollutants and habitat modification (ASMFC 2004). These concerns have prompted recognition of the need for identification, conservation and restoration of habitats critical to Atlantic menhaden survival and recruitment.

The objective of this study is to combine site-specific abundance and growth rate estimates to quantify relative habitat production in the Chesapeake and Delaware Bays. These values can be used to compare relative habitat qualities for Atlantic menhaden as well as investigate associations between juvenile menhaden dynamics and environmental factors. A central goal was to determine whether there are specific sites that promote consistently high production and represent high quality habitats.

Materials and Methods

Field

Field sampling for young-of-the-year Atlantic menhaden was conducted periodically between June 6 – November 20, 2007 and between June 11 – November 17, 2008. Sampling was conducted by scientists from the Chesapeake Biological

Laboratory (CBL), the New Jersey Department of Environmental Protection (NJDEP), the Maryland Department of Natural Resources (MDNR), the Virginia Institute of Marine Science (VIMS) and the University of Delaware (UD). Sampling protocols were standardized among institutions. In the Delaware Bay, sampling was conducted in the lower Delaware River and upper Delaware Bay (Figure 4.1). In the Chesapeake Bay, samples were collected from the Northeast River, Susquehanna Flats, Bohemia River, Elk River, Sassafras River, Worton Creek, Chester River, Tuckahoe Creek, Choptank River, Patuxent River, Nanticoke River, Potomac River and James River (Figure 4.1). In our analysis, the Northeast River, Susquehanna Flats, Bohemia River, Elk River, Sassafras River and Worton Creek were classified as Upper Bay. Thus analyses involved eight distinct systems: Delaware Bay, Upper Chesapeake Bay, and the Chester, Choptank, Patuxent, Nanticoke, Potomac and James Rivers.

NJDEP sampling sites included both fixed and stratified random station locations throughout the Delaware River (Figure 4.1) sampled periodically from June – November in 2007 and 2008. At each sampling site, a 30.5 m beach seine with 6.4 mm mesh was deployed and the number of age-0 menhaden captured in each haul was quantified. A random subsample of up to ten menhaden from each catch was preserved on dry ice, then stored at -80°C for subsequent biochemical analysis. For subsequent abundance calculations, a value of 729 m² was used as the area swept by each seine haul. Surface water temperature, salinity and dissolved oxygen were also measured.

MDNR sampling sites consisted of fixed locations in the upper Chesapeake Bay, and the Choptank, Patuxent, Nanticoke and Potomac River systems (Figure 4.1). These sites were sampled monthly from July – September in 2007. MDNR did not provide any samples in 2008. At each site, samples were collected using duplicate hauls of a 30.5 m beach seine with 6.4 mm mesh. The number of age-0 menhaden in each haul was quantified. A random subsample of ten menhaden from each catch was preserved on dry ice, then stored at -80°C for subsequent biochemical analysis. For abundance calculations, a value of 729 m^2 was used for the area of each haul. Time of first haul, maximum distance from shore, weather, maximum depth, surface water temperature, tidal stage, surface salinity, dissolved oxygen, pH and turbidity measurements were recorded at each site.

VIMS sampling sites were located in the James River (Figure 4.1) and were sampled periodically from July – September 2008. At each site, duplicate hauls of a 30.5 m beach seine with 6.4 mm mesh were deployed perpendicular to the shoreline (either until the net was fully extended or a depth of approximately four feet was encountered) and then leaving the onshore brail in a fixed position while pulling the offshore end down current and back to the shore, resulting in the sweeping of a quarter circle quadrant (Hewitt et al. 2008). The number of age-0 menhaden in each haul was quantified and a random subsample of up to ten menhaden from each haul was preserved on dry ice, then stored at -80°C for subsequent biochemical analysis. A haul area of 729 m^2 was used for abundance calculations. Water temperature, salinity, dissolved oxygen, pH, sampling time, tidal stage and weather conditions were recorded.

CBL sampling sites consisted of 12 sites in the Patuxent River, MD (Figure 4.1) which were sampled at least monthly between June - November in both 2007 and 2008. Additionally, CBL project staff conducted seining in the Choptank, Chester and upper Chesapeake Bay tributary systems monthly July – November 2008 (Figure 4.1). At each site a 30.5 m beach seine with 6.4 mm mesh was deployed. The shore length of the haul as well as maximum seine extension distance from shore was recorded and used to calculate the area (m²) swept by each haul. The number of young-of-the-year menhaden collected in each haul was quantified. A random subsample of up to ten menhaden from each haul was preserved in liquid nitrogen, then stored at -80°C for subsequent biochemical analysis. Water temperature, salinity and dissolved oxygen were measured using a YSI Professional Plus (Yellow Springs, OH) and time of haul and tidal stage were recorded.

University of Delaware personnel sampled in multiple sites in the Delaware estuary (Figure 4.1) periodically August – October 2008. At each site, a 30.5 m beach seine with 6.3 mm mesh was deployed at two locations, separated by approximately 500 m. An area swept of 729 m² was assumed for each haul. The number of menhaden collected in each haul was quantified. A subsample of menhaden from each catch was taken at random and preserved on dry ice, then stored at -80°C for subsequent biochemical analysis.

Laboratory

The RNA:DNA levels of samples collected from the field were analyzed following the protocol described in Chapter 2. Briefly, RNA and DNA content of white muscle tissue were quantified using the 1 dye/2 enzyme microplate

fluorometric assay. I verified that sample degradation does not occur as a result of storage at -80C. I determined the relationship between RNA:DNA, temperature and growth rate (manipulated through feeding treatments) in laboratory experiments (Chapter 2). The instantaneous growth rate of juvenile Atlantic menhaden was predicted as:

$$G = 0.01021(RNA:DNA) + 0.00199(Temp) - 0.09929, n = 48, \text{ adj } R^2 = 0.76 \quad (1)$$

Statistics

The predicted growth rates of all individuals collected at a site during a specific sampling event were averaged to estimate the site-specific mean instantaneous growth rate (G , d^{-1}). The abundance (A , number of fish. m^{-2}) of each sampling site was calculated, as well as the mean body mass (\bar{W} , g) of individuals at each site. Using these, instantaneous site-specific production (P , $g \cdot m^{-2} \cdot d^{-1}$) was calculated as:

$$P = G \cdot \bar{W} \cdot A \quad (2)$$

Due to unavoidable logistical constraints, estimates of growth, abundance and subsequent production were not available for all sites at all sampling periods, producing an unbalanced inventory of habitat estimates. This precluded the use of parametric statistical methods. Because a central goal of our analyses was to identify whether individual sites consistently supported high levels of production, I chose to use a Z -score transformation of the data that allowed the relative ranking of each sample to be assessed. Z -scores are standardized values obtained by dividing the difference between the population mean and an individual value by the population standard deviation. This transformation allows comparison of values from different

distributions. Because these values are standardized in units of standard deviation, positive z-scores represent values above the mean, negative scores represent values below the mean and a score of zero represents no deviation from the mean.

Comparisons between sites and systems were conducted using standard scores (Z-scores). Sampling was conducted on a biweekly basis, and thus Z-scores estimates were scaled using half-monthly increments. This ensures that Z-score values of sites were calculated from only a single sampling event. For sites sampled within a given half-monthly period, estimates of growth, abundance and production were standardized using the equation:

$$Z_{ijk} = \frac{X_{ijk} - \bar{X}_{ijk}}{\sigma_{X_k}} \quad (3)$$

Where X is the site-specific habitat estimate, \bar{X} is the mean of the distribution of all site-specific habitat estimates from the given half-monthly period and σ is standard deviation of the mean site-specific habitat estimates. This transformation allows for a relative comparison of site-specific estimates based on an average habitat score ($\bar{Z}_k = 0$).

Pearson product moment correlation analysis was used to examine the relationships between site mean instantaneous growth rate, abundance, mean body mass and production. Pearson correlation analysis was also used to examine relationships between site mean instantaneous growth rate, abundance and production and corresponding temperature and salinity measurements recorded at the time of sampling events.

Results

A total of 328 and 715 individual fish were analyzed for RNA:DNA and subsequent growth in 2007 and 2008, respectively. Between June – November 2007, seining was conducted at 74 distinct sampling sites across six systems in the Chesapeake and Delaware Bays: Delaware Bay (n = 32), Upper Bay (n = 12), Choptank (n = 4), Patuxent (n = 15), Nanticoke (n = 4) and Potomac (n = 7) (Table 4.1). In 2008, seining was conducted at 100 sites across seven systems: Delaware Bay (n = 39), Upper Bay (n = 9), Chester (n = 11), Choptank (n = 15), Patuxent (n = 12), Nanticoke (n = 3) and James (n = 11) (Table 4.2). In both years, site-specific mean instantaneous growth ($n_{07} = 47$, $n_{08} = 96$), abundance ($n_{07} = 513$, $n_{08} = 526$) and production ($n_{07} = 430$, $n_{08} = 434$) were estimated for each sampling event (Tables 4.1 & 4.2).

Field based estimates of RNA:DNA were broadly similar to those measured in laboratory calibration experiments (Fig. 4.2), and thus resultant estimates of growth were derived from interpolation of Eq. 1 rather than extrapolation. RNA:DNA levels in individual menhaden ranged from 1.759 – 11.817 (Figure 4.2.A). RNA:DNA-based predicted instantaneous growth rates of individual menhaden were between -0.035 – 0.078 d^{-1} , and as with RNA:DNA values, were similar to those measured in the laboratory (Figure 4.3).

Individual site-specific mean growth (d^{-1} , \pm S.E.) varied from -0.023 ± 0.005 – 0.030 ± 0.003 in 2007 and -0.022 ± 0.004 – 0.048 ± 0.008 in 2008 (Tables 4.1 & 4.2). In both years, individual site mean instantaneous growth declined throughout the season (Figure 4.4); however, the majority of instantaneous growth rates were

positive in 2007 (57.4%) and 2008 (62.5%). No perceivable pattern in relation to a latitudinal gradient existed in either year (Appendix A & D). In 2007, system-level growth estimates were available for the Delaware Bay, Choptank and Patuxent systems, although the Choptank was only represented by a single site. Generally, juvenile menhaden in the Patuxent outperformed those in the Delaware Bay in terms of instantaneous growth in 2007 (Figure 4.5). In 2008, the availability of growth estimates was more spatially extensive. Based upon the distribution of standard Z-score estimates, the Upper Bay, Chester and Patuxent systems typically supported lower growth while the Delaware, Choptank, Nanticoke and James generally exhibited higher growth (Figure 4.6). It should be noted that relatively high growth estimates from the Nanticoke are likely a result of having only three samples from early in the season, and the James system is represented by only one sampling site.

Site-specific instantaneous growth in both years was variable (Figures 4.7 & 4.8). In 2007, eight sites from the Delaware, Choptank and Patuxent systems were represented by an estimate of growth from a single biweekly sampling event, and thus do not provide a reliable basis by which to determine if these sites exhibited a consistent ranking with respect to growth. Estimates of growth from multiple biweekly sampling events were available for 12 sites from the Delaware and Patuxent systems in 2007. These data indicate that individual sites within these systems tended to be either highly variable or consistently low in the relative growth they supported. For example, growth estimates for the Chester Island (CI) site in the Delaware Bay were either the most highly ranked during one biweekly sampling period, or one of the lowest ranked during another biweekly sampling (Figure 4.7, Table 4.3). In

contrast, growth estimates for the Helms Cove (HC) site in the Delaware Bay system when sampled were consistently 0.5 - 1 standard deviation units below the median for all sites sampled in the respective biweekly periods (Figure 4.7, Table 4.3). In 2008, estimates of growth from single biweekly sampling events were represented by 23 sites, and multiple biweekly sampling events were also available for 23 sites (Table 4.4). A similar pattern was observed in 2008 as individual site relative growth was either highly variable or consistently low (Figure 4.8).

There was no relationship between the Z-scores for instantaneous growth in 2007 and 2008 for sites at which data were available from multiple biweekly sampling events and available in both years (Figure 4.9). However, this finding is strongly influenced by data from a single site in Delaware Bay (Augustine Beach – AB). This site supported the lowest average growth in 2007 and one of the highest average growths in 2008 of those sites sampled consistently in both years. If the AB data are considered anomalous, then the correlation between site-specific average growth in the two years is significant ($R^2 = 0.388$, $p < 0.05$, $n = 10$).

The number of menhaden collected in seine hauls varied from 0 – 1,330 in 2007 and 0 – 5,050 in 2008. Individual site-specific mean abundances varied from 0 – 0.95 fish.m⁻² in 2007 and 0 – 7.65 fish.m⁻² in 2008 (Tables 4.1 and 4.2). Menhaden abundance varied without trend in both years, but was generally more variable in 2008 (Figure 4.10). In neither 2007 nor 2008 was a latitudinal gradient in fish abundance observed (Appendix B & E). System-level comparisons of abundance are complicated by the high frequency of zero catches. Given this caveat, median abundance estimates for 2007 exhibited little variation among systems; however, the

Nanticoke system was generally the highest, with the Patuxent and Delaware Bay systems exhibiting the most variability (Figure 4.11). System-level abundances in 2008 displayed patterns similar to the preceding year; however, as with growth, the Nanticoke system abundance is driven by limited sampling occurring only in June (Figure 4.12).

As noted with system-level abundance comparison, site-specific comparisons of abundance are also complicated by the high frequency of zero catches. This attribute of the data tends to dampen potential differences in medians among sites. Given this, it was particularly striking that in 2007 three sites in the Nanticoke (LL – Lewis Landing, CP – Chapter Point, TB – Tyaskin Beach) and one site in the Choptank (NS – North Shore) exhibited consistently high levels of relative abundance of juvenile menhaden (Figure 4.13, Table 4.3). In 2008, site-specific median abundance levels were broadly similar (Figure 4.14, Table 4.4).

There was no relationship between the Z-scores for abundance in 2007 and 2008 for sites at which data were available from multiple biweekly sampling events and available in both years (Figure 4.15). Only at sites Fort Mott (FM) in the Delaware Bay and Cage Stables (CS) in the Patuxent did relative abundance increase from below- to above-average.

Based on RNA:DNA-based estimates of the instantaneous growth rates of individual menhaden, their size and estimated abundances within specific habitats, site-specific production was calculated using Eq. 2. Site mean production ranged from $-0.183 - 0.038 \text{ g.m}^{-2}.\text{d}^{-1}$ in 2007 and $-0.437 - 0.744 \text{ g.m}^{-2}.\text{d}^{-1}$ in 2008 (Tables 4.1 & 4.2), and was relatively variable in 2008 (Figure 4.16). As with growth and

abundance estimates, no trends in monthly habitat-specific production related to latitude were distinguishable (Appendix C & F). Aside from the production estimate for the Nanticoke system in 2008, which was inflated because the dominance of early season sampling, there was limited variability in system-specific levels of production in either year (Figures 4.17 & 4.18).

Similar to abundance, site-specific production estimates were influenced by the prevalence of zero-abundance sampling events, although Z-scores did identify some sites with relatively increased or decreased production throughout the season (Figures 4.19 & 4.20). In particular, consistently low levels of relative production were observed in some Delaware Bay sites previously identified as supporting consistently low growth rates in 2007 (HC - Helms Cove, NC – Newcastle)(Figure 4.19, Table 4.3). In 2008, inter-site variability in growth was not sufficient to alter the template for production established by patterns in abundance (Figure 4.20, Table 4.4).

The comparison of site-specific production for sites at which data were available in both years and multiple biweekly sampling events is complicated by the extremely high relative production observed in Tim's Creek in the Upper Bay in 2008. However, with or without this site, no clear correlation exists between site-specific productions in the two years (Figure 4.21).

Pearson product moment correlation analysis showed similar relationships among estimates of growth, abundance and production in 2007 and 2008 (Tables 4.5 & 4.6). A nonsignificant positive correlation was observed between instantaneous growth rate and abundance in both years ($r_{07} = 0.228$; $p_{07} = 0.1234$; $r_{08} = 0.152$; $p_{08} =$

0.1381 – Figures 4.22 & 4.23). There were significant negative relationships between growth and mean weight ($r_{07} = -0.526$; $p_{07} < 0.001$; $r_{08} = -0.384$; $p_{08} < 0.0001$).

Growth rates and production were also significantly correlated in 2007 and 2008 ($r_{07} = 0.348$; $p_{07} = 0.0164$; $r_{08} = 0.422$; $p_{08} < 0.0001$ – Figures 4.24 & 4.25). In 2007, a significant negative correlation was found between abundance and production ($r = -0.139$; $p = 0.0038$ – Figure 4.26); however, a significant positive relationship was present in 2008 ($r = 0.279$; $p < 0.0001$ – Figure 4.27). In both years mean weight and production were negatively correlated ($r_{07} = -0.415$; $p_{07} = 0.0037$; $r_{08} = -0.242$; $p_{08} = 0.0178$).

Pearson product moment correlation analysis found temperature and salinity to be significantly correlated to site specific abundance and instantaneous growth rate, but not to production (Figure 4.28). Positive significant correlations were observed between temperature and both abundance ($r = 0.068$; $p = 0.03$) and growth ($r = 0.486$; $p < 0.0001$). However, temperature and production were not significantly correlated ($r = 0.06$; $p = 0.074$). Similarly, salinity was significantly correlated to abundance ($r = 0.103$; $p = 0.001$) and growth ($r = -0.226$; $p = 0.0065$), but not to production ($r = -0.017$; $p = 0.62$).

Discussion

Several studies have incorporated biochemical indices (RNA:DNA) into their habitat evaluation; however, most have used these measures as either a qualitative proxy for condition (Gilliers et al. 2004, Fonseca et al. 2006, Meng et al. 2008, Vinagre et al. 2008, Vasconcelos et al. 2009) or to generate a correlative growth rate as an exclusive indicator of habitat quality (Malloy et al. 1996, Yamashita et al. 2003,

Stierhoff et al. 2009). By coupling RNA:DNA-based estimates of growth and field-based abundance estimates, this study represents one of the few to formally quantify habitat-specific production to assess spatiotemporal variability in habitat quality. To our knowledge, this is the first study to examine habitat-specific production in Atlantic menhaden.

Most RNA:DNA and instantaneous growth measurements collected from the field fell within range of those observed in the laboratory. Fish in the field will often grow faster than those under laboratory conditions, and this can be a source of bias in growth and production estimates (Folkvord 2005). The results of this study indicate that the spectrum of RNA:DNA and growth produced in the laboratory was sufficiently broad to encompass the vast majority of growth conditions experienced by juvenile menhaden in the environment, and thereby provide an appropriate foundation from which to estimate production.

In both 2007 and 2008, broad-scale (system-level) estimates of growth, abundance and production exhibited considerable temporal and spatial variability. Generally, system-wide growth rates declined throughout the growing season; whereas abundance displayed no apparent trend over time. As a result, abundance tended to drive variability of production estimates. System-specific patterns in production were difficult to quantify because of the impact of numerous zero catches in the data. However, site-specific comparison did reveal some sites that appeared to support consistently high levels of production compared to other sites in 2007. Site-specific differences in production were less evident in 2008. For all estimates (growth, abundance and production) no latitudinal gradients within a system were

apparent, neither was there evidence of gradation extending from a central point of high production. In fact, in some instances sampling sites located sequentially along the latitudinal gradient could produce vastly different estimates of growth, abundance and production.

A central goal of this research was to explore whether individual sites consistently exhibited relatively high levels of menhaden production. The results presented here indicate that although there was substantial spatial and temporal variability in menhaden production in 2007 and 2008, no single site consistently exhibited the highest level of production. Our analyses do not support the notion that individual sites defined at a small spatial resolution within broad estuarine areas serve as nurseries *sensu* Beck et al (2001). I suggest it is more likely that juvenile menhaden utilize a mosaic of sites within broad estuarine areas to promote growth, survival and production. Friedland et al. (1996) suggest the distribution of juvenile menhaden may vary over space and time in relation to various factors, most notably phytoplankton concentrations. Although associations with environmental factors have yet to be comprehensively examined in our study, it is possible that complex interactions between biotic and abiotic factors may influence the observed habitat-specific estimates of growth, abundance and production. These factors themselves can exhibit high spatiotemporal variability throughout the estuarine environment, and thus may contribute to the high variability in our site-specific estimates.

If juvenile menhaden rely on a mosaic of habitats to promote production as suggested by our results, defining those habitats that are “essential” will require sampling that is both spatially and temporally intensive. Simply stated, fisheries

biologists and managers cannot rank and compare the relative value of sites for production of menhaden based on a limited spatial or temporal sampling scheme. Given the high spatiotemporal variability of menhaden production throughout the estuarine environment, defining essential fisheries habitat for the purposes of protection or restoration of specific areas may prove problematic. The results of this investigation suggest that the designation of specific geographic areas within estuaries as preferred nursery habitats for juvenile menhaden may be difficult, if not impossible. Perhaps more useful to management objectives would be the identification of factors contributing to the site-specific variability observed in menhaden production, as echoed by Beck et al. (2001). If driving factors can be reliably determined and the spatiotemporal behavior in these factors can be predicted throughout the estuarine environment, the patterns of menhaden production may be simulated to provide a more dynamic assessment of important nursery habitats.

Based upon coefficient of variation (CV), the variation in 2007 site-specific production estimates was driven in nearly equal magnitude by instantaneous growth rates (CV = 5.06) and site-specific abundance (CV = 5.45). Conversely, 2008 production estimates were influenced more by abundance (CV = 6.74) than by growth rates (CV = 2.10). Similar high levels of variability in abundance have been observed for Atlantic menhaden in other studies (Wingate & Secor 2008). Mean individual body weight contributed relatively little to the observed variation in production in both years (CV₂₀₀₇ = 0.91, CV₂₀₀₈ = 0.60). Nonsignificant positive correlations were observed between instantaneous growth and abundance in both years, suggesting that growth rate is independent of fish abundance in menhaden at fine spatial and

temporal scales. In both years, growth rate and mean body weight were negatively correlated, likely a result of decreased potential for somatic growth with increasing body mass coupled with decreasing water temperatures as the growing season progressed. Correlations between production and any one of the factors used to estimate it are inherently influenced by one another due to the multiplicative properties of the production equation; however, aside from the relationship between abundance and production in 2007, similar patterns were observed between years. A significant negative correlation was observed between abundance and production in 2007. This pattern is likely driven by a single data point observed late in the growing season (10/11/07) consisting of several large individuals experiencing relatively low growth. If this data point is removed, there is a positive correlation between abundance and production, as was observed in 2008.

It is important to note that my conclusions regarding temporal and spatial variability in production are heavily dependent on interpretation of zero catches in the biweekly sampling in the surveys. I interpreted zero hauls as true zero values, giving them full weight in my analyses. The high frequency of zero hauls served to constrain estimates of the median abundance and thus of the median levels of production. I believe this is the most conservative approach. However, I recognize that a zero haul does not necessarily reflect the absence of menhaden in the habitat. Several factors may cause a zero haul even when menhaden are present. Most fisheries sampling inherently assumes that fish are randomly distributed, with each individual having an equal probability of being caught. Menhaden's schooling behavior violates this assumption and tends to produce catches that are bimodally

distributed. This precluded the use of parametric statistics, but application of Z-transformations may still be susceptible to this source of bias, potentially inflating or deflating estimates. Additionally, a beach seine is likely not the optimal gear for sampling juvenile menhaden. The depth restriction on seining may have reduced the likelihood of sampling menhaden, particularly later in the year.

Due to the importance of estuarine environments to the growth and survival of fish early life stages and subsequent year class success, as well as the ever-increasing vulnerability of estuarine habitats to anthropogenic disturbance, the identification and classification of essential fish habitat has become a priority in fisheries research. Defining EFH requires data on habitat-specific abundance, growth, survival and production; the latter proving the most difficult to obtain (Able 1999). Numerous studies have attempted to assess and evaluate habitat quality by comparing relative growth (Sogard 1992, Malloy et al. 1996, Able et al. 1999, Duffy-Anderson & Able 1999, Meng et al. 2000, Nislow & Folt 2000, Phelan et al. 2000, Manderson et al. 2002, Amara et al. 2007, Glass et al. 2008, Meng et al. 2008), fish size (Le Pape et al. 2003), abundance (Fodrie & Mendoza 2006, Courrat et al. 2009), or a combination of growth and abundance estimates (Gilliers et al. 2006, Taylor et al. 2007). However, few have attempted to evaluate fish habitat by calculating potential production or contribution (Kraus & Secor 2005), which has been suggested as the most useful measure of nursery quality (Beck et al. 2001).

The estuarine environment is highly dynamic in terms of the biotic and abiotic factors and related processes influencing the growth, abundance and subsequent production of juvenile fish nursery habitats. Therefore, methods used to quantify

habitat-specific production must operate on similar fine spatial and temporal scales. However, year-class success and overall contribution to the adult populations are based on the cumulative input from habitats over large spatial and temporal scales. To examine such population-level processes, estimates of production from putative nursery habitats must be available over a sufficiently broad range to encompass dynamics relevant to the population of interest. Gilliers et al. (2006) suggest a meso-scale approach to examine general trends followed by a more precise investigation on the local scale to understand causative dynamics. The highly variable estimates observed at both broad- and fine-scale levels in this study suggest the need to quantify potential abiotic and biotic factors influencing production in the estuarine environment. The high spatial and temporal variability observed at the site-specific level in this study may be attributed to fine-scale spatiotemporal variation of numerous environmental factors, characteristic of the estuarine environment.

A number of studies have noted associations between areas of increased phytoplankton production and menhaden abundance and growth (Friedland et al. 1989, Friedland et al. 1996, Luo et al. 2001, Brandt & Mason 2003, Love et al. 2006). These areas of high phytoplankton biomass have been found to move in relation to changes in flow rates as the season progresses in the estuary mainstem as well as associated tributaries (Friedland et al. 1996). Additionally, as menhaden grow, morphological changes in feeding apparatus, swimming speed and energetic requirements shift feeding strategies away from high concentrations of nanophytoplankton, located in the upper estuary, to larger and less concentrated plankton found in lower estuary and coastal areas, potentially driving menhaden

down estuary (Friedland et al. 1996). The interactions between spatiotemporal variability in phytoplankton biomass and changes in menhaden behavior will likely influence the growth, abundance and production during juvenile occupancy and may partly explain the high variability observed in our results. Salinity has also been offered as a potential factor influencing the growth and distribution of juvenile Atlantic menhaden. It has been proposed that menhaden during early-life prefer low salinity environments in which to metamorphose to juvenile stages (Wilkens & Lewis 1971, Weinstein 1979, Rogers et al. 1984, Murdy et al. 1997) after which they are increasingly found in higher salinity areas (Lewis et al. 1972). In laboratory experiments, Hettler (1976) also found that juvenile menhaden in lower salinities outperformed their conspecifics raised in higher salinities. However, Love et al. (2006) failed to observe a pattern in distribution of menhaden in relation to salinity. Although latitudinal patterns (an imprecise proxy for salinity) were not apparent, significant correlations were observed between salinity and both site-specific abundance and growth in this study. However, more comprehensive examinations of trends with salinity are desired. Anthropogenic disturbances have the potential to alter nursery habitat in estuarine environments, and such disturbances have been suggested as a possible culprit of site-specific declines in menhaden recruitment (Love et al. 2006). It is possible that local land-use patterns may be at least partly responsible for the observed site-specific variability observed in this study. An investigation of potential human-induced habitat alteration in relation to specific nursery areas may help to elucidate relationships. Ultimately, the patterns of habitat use by juvenile Atlantic menhaden are likely driven by a combination of numerous

environmental factors known to influence the growth and production of fishes. Manderson et al. (2002) found that habitat suitability in terms of growth of juvenile winter flounder varied greatly in space and time and that the highest quality areas coincided with areas of optimal temperature and salinity intersection. Future work to link observed patterns in growth, abundance and production of juvenile menhaden nursery habitats may help to identify the environmental conditions influencing nursery habitat contribution and recruitment success. Evaluating these mechanisms may improve management and increase understanding of the population dynamics of this ecologically and economically important species.

Table 4.1. Site-specific data from each sampling event in 2007.

System	Site Code	Latitude	Longitude	Date	Temperature (°C)	Salinity (ppt)	Abundance (fish.m ⁻²)	Weight (g)		RNA:DNA		G (d ⁻¹)		Production (g.m ⁻² .d ⁻¹)

Chapter 5:

Conclusions, limitations and future work

The objective of this chapter is to integrate the information presented in the previous four chapters, identify potential limitations of the study and describe future research objectives. Chapter 1 introduced the objectives of the projects included in this thesis. It reviewed the nursery-role hypothesis and the need for reliable estimates of site-specific production to identify essential fish habitats. A nucleic acid-based index, specifically RNA:DNA, was identified as a potential measure of assessing growth on spatial and temporal scales relevant to habitat residency. The life history of Atlantic menhaden was described, as well as the importance of identifying mechanisms influencing the success of this species during estuarine residency. Chapter 2 “An RNA:DNA-based model for estimating growth rate of juvenile Atlantic menhaden *Brevoortia tyrannus*” used laboratory experiments to quantify the relationships between RNA:DNA, temperature, feeding and growth rate, and developed a predictive RNA:DNA-based model for use on field-collected individuals. Chapter 3 “Temporal response (latency) of RNA-DNA ratio to changes in feeding regime in juvenile Atlantic menhaden *Brevoortia tyrannus*” investigated the utility of a predictive model to assess habitat-specific growth and production by using laboratory experiments to quantify the temporal response of RNA:DNA to changes in feeding. Finally, Chapter 4 “A preliminary assessment of broad- and fine-scale patterns in RNA:DNA-based growth, abundance and production of juvenile Atlantic menhaden in the Chesapeake and Delaware Bays” investigated the applicability of the model developed in Chapter 2 to field-collected individuals, and examined the spatiotemporal variability in juvenile Atlantic menhaden growth, abundance and production at the system- and site-level.

The focal point of the second chapter, “Relationship of RNA-DNA ratio and water temperature to growth rates in juvenile Atlantic menhaden *Brevoortia tyrannus*” was the development of an RNA:DNA-based predictive model of growth for juvenile Atlantic menhaden. Recruitment success of this species is likely greatly influenced during periods of early life (Quinlan & Crowder 1999) and defining essential fish habitat as well as identifying factors affecting juveniles during estuarine residency will provide a more comprehensive understanding of the recruitment dynamics of this species. The predictive model developed in this study provides a means of quantifying growth and subsequent production in relation to biotic and abiotic factors present at the time of sampling events. This tool allows for the relative comparison of juvenile menhaden habitat quality in the estuarine environment, assessment of the spatiotemporal variability of menhaden growth and production, and the identification of factors potentially influencing observed variability.

Due to unavoidable logistical constraints in terms of experimental design some important factors potentially influencing the RNA:DNA-growth relationship could not be investigated. Some studies have suggested food quality (Lied & Rosenlund 1984), food quantity (Goolish et al. 1984, McMillan & Houlihan 1988) and salinity (Kim et al. 2008) as potential influential factors in nucleic acid-growth relationships. Menhaden are obligate filter-feeders which consume plankton in the natural environment (Jeffries 1975). However, to maintain consistent ration treatments during experimentation, fish were fed a finfish starter meal similar to other laboratory studies on this species (McNatt & Rice 2004). Differences in energetic quality between natural prey for juvenile menhaden and food provided in experiments

may produce different rates of growth; however, I feel confident my methods did not bias results as feeding-related influences on the RNA:DNA-growth model were not quantified. Additionally, reliable estimates of food concentration in the field would likely prove difficult to obtain and thus, were excluded from the predictive model. Salinity represents an important factor influencing the vital rates of fishes in a variety of ways (Wooten 1998); however, effects of salinity are often ignored in RNA:DNA-growth relationships. Hettler (1976) noted effects of salinity on the growth and metabolic rates of juvenile menhaden. It is possible that salinity could influence my model; however potential affects could not be quantified in the present study.

Despite these limitations, the model developed in this study explained a considerable amount of the variability in growth (76%), comparable to nucleic acid-based growth indices produced in other studies. However, the model has yet to be tested on subjects with known growth rates from an independent sample. Model validation is desired where known measurements of growth from independent trials are directly compared with model predictions. Such testing may help to identify potential biases and improve model development.

Chapter 3, “Temporal response (latency) of RNA-DNA ratio to changes in feeding regime in juvenile Atlantic menhaden *Brevoortia tyrannus*” quantified the responsiveness of RNA:DNA to nutritional condition in this species. The utility of RNA:DNA-based growth indices lies in their ability to estimate recent growth in relation to specific-habitat residency and related environmental factors. However, to reliably associate patterns in RNA:DNA-based growth to specific sites and/or biotic and abiotic variables, the temporal response of RNA:DNA must first be determined.

This study detected changes in RNA:DNA in response to feeding conditions within two days and significant differences were observed in as little as four days. These results support the ability of my predictive model to estimate growth on small temporal scales relative to specific habitat residency. However, further work is desired to more comprehensively quantify the latency dynamics of juvenile menhaden.

Due to logistical constraints, only one temperature could be employed to produce sufficient replication of treatments conditions. To represent an approximate median temperature of Chesapeake and Delaware Bays during menhaden estuarine residency, 24°C was chosen. However, the temperature dynamics in estuarine environments are both spatially and temporally variable and juvenile menhaden will ultimately experience a spectrum of thermal regimes. Because RNA:DNA-growth relationships are often influenced by temperature (Buckley 1982, Buckley et al. 1984, Caldarone et al. 2003, Caldarone 2005, Mercaldo-Allen et al. 2006), it is possible that the temporal response of RNA:DNA in menhaden will vary at different temperatures, as seen previously in other fishes (Jurss et al. 1987, Malloy & Targett 1994a). Further experimentation incorporating a range of possible thermal scenarios may help to elucidate potential interactions between temperature and the latency of RNA:DNA in juvenile menhaden.

The predictive model developed in Chapter 2 was intended for use throughout the entire size range of young-of-the-year menhaden during estuarine residence. However, the size range incorporated in our temporal response experiment was less broad. Menhaden of varying sizes will likely display variable responses to stressors,

such as changes in feeding conditions, due to differential energy reserves and metabolic requirements. For example, Rooker & Holt (1996) found that RNA:DNA in red drum was less responsive to starvation as fish became older. Differential temporal responses of RNA:DNA between individuals may lead to incorrect assumptions regarding the scale of observed RNA:DNA-based estimates. Further quantification of the latency of RNA:DNA of individuals within a more complete size spectrum is desired to determine if inferences regarding the scale of RNA:DNA-based estimates can be reliably applied to all size-classes of juveniles found in the estuarine environment.

It is entirely likely that changes in condition (e.g. feeding) in the natural environment are less pronounced than those experienced by individuals in my latency trial. If so, changes in growth and subsequent RNA:DNA values in the field may be more subtle. To reliably assess site-specific growth and associated environmental factors, my RNA:DNA-index must be sufficiently sensitive to detect such minuscule changes. Johnson et al. (2002) observed declines in RNA:DNA in response to relatively large changes in feeding level, but failed to detect changes at intermediate feeding regimes. This inability to detect subtle changes may bias field-based estimates and fail to fully capture the dynamics of the system being investigated. To address this concern, further experimentation is desired incorporating intermediate feeding similar to Wright & Martin (1985), Arndt et al. (1996) and Johnson et al. (2002).

Despite inherent limitations, this study has successfully established the rapid response of RNA:DNA to changes in feeding in juvenile Atlantic menhaden. These

finding suggest the utility of the predictive model to assess short term growth and production and provides a preliminary foundation for further investigation of the latency of RNA:DNA under other scenarios for this species.

Chapter 4, “A preliminary assessment of broad- and fine-scale patterns in RNA:DNA-based growth, abundance and production of juvenile Atlantic menhaden in the Chesapeake and Delaware Bays” assessed the spatiotemporally variability of potential juvenile Atlantic menhaden nursery habitats. By combining RNA:DNA-based estimates of growth from field-collected individuals and site-specific abundance estimates from surveys, production of sites within the Chesapeake and Delaware Bays was calculated. This chapter explored the central objective of the research – to determine whether specific sites within the estuarine environment consistently exhibited high levels of menhaden production. Beck et al. (2001) propose that nursery habitats are those areas that on average contribute disproportionately more recruits than others, and suggest production as the best integrative measure to evaluate this contribution. The results of my investigation suggest that juvenile menhaden contribution is not simply a result of consistently high production of specific-sites, but rather, the utilization of many sites by menhaden over space and time. These findings have important implications to management and the definition of essential fisheries habitat for this species. High spatiotemporal variability in menhaden production throughout estuaries may preclude the designation of specific-sites as EFH. However, identifying the causative factors and understanding mechanisms contributing to observed variability in production may provide valuable insights into the population dynamics of this species. If the

spatiotemporal variability of important factors can be accurately predicted, mapping of potential juvenile menhaden production throughout the estuarine environment may be achieved, producing a spatiotemporally dynamic depiction of relative habitat quality and assisting in the forecasting of recruitment outcomes.

In conclusion, my research has provided a foundation for further investigation into the production dynamics of juvenile Atlantic menhaden in the estuarine environment. The RNA:DNA-based index of growth developed in Chapter 2 and the quantification of the temporal response of RNA:DNA in Chapter 3 provide a potentially valuable tool for estimating short term growth of menhaden in relation to specific habitat residency. Using the estimates derived from this model, a preliminary assessment of the spatial and temporal variability in juvenile menhaden production was conducted in Chapter 4. Results of this investigation suggest a highly variable utilization of estuarine habitats over space and time, exemplifying the need to identify the causative agents driving observed variability in juvenile menhaden production. Future research may improve our understanding of the relationships between menhaden production and important biotic and abiotic factors, potentially enhancing our knowledge of population dynamics and improving management strategies for Atlantic menhaden.
